## Abstract

Lateral shortening is expressed in unique ways in salt basins, especially if pre-shortening diapirs are present. We present an overview and new 3-D conceptual models capturing the evolution of shortening structures formed in salt provinces dominated by precursor isolated diapirs (termed *isolated-diapir provinces*). In such provinces, isolated diapirs form only a minor volumetric component of a sedimentary basin, however, due to the relative weakness of rock salt and their ability to localize strain, during shortening they have a disproportionately large influence on structural development.

We find three key mechanical principles govern the processes and structural styles developed during shortening of isolated-diapir provinces. First, salt diapirs shorten before surrounding sedimentary rocks due to their relative weakness, and so form salients in the thrust front during early shortening. Second, diapirs tend to nucleate folds and faults, which radiate out from the diapirs. Third, as diapir walls converge, the roof must shorten. Extrusive salt sheets are expelled through thin roofs, but thicker roofs resist piercement and so tend to undergo complex folding and faulting.

As a result of these principles, the first-order controls on the structural styles expressed across a shortened isolated-diapir province are the pre-shortening configuration of diapirs, the connectivity of the diapirs prior to shortening, total strain magnitude, and diapir roof thickness. Second-order controls include the initial cross-sectional and map-view geometry of diapirs, diapir size, and diapir orientation with respect to the shortening direction.

## 1. Introduction

The geometry and kinematics of fold-and-thrust belts are generally well understood as a result of their spectacular exposure in mountain ranges around the world (e.g., Bally et al., 1966; Dahlstrom, 1969; Boyer and Elliott, 1982). A relatively poorly-understood aspect of these systems involves fold-and-thrust belts that detach on, and are influenced by mobile salt. In these settings 3-D shortening styles can be particularly complex and diverse due to: i) salt being much weaker than local sedimentary rocks, creating a strength anisotropy during shortening; and ii) the ability of salt to flow and thus be heterogeneously distributed prior to the onset of shortening (e.g. Davis and Engelder, 1985; Letouzey et al., 1995). Thus, the configuration of salt prior to shortening exerts a major control on salt-detached structural styles, with three styles standing out.

In the first and simplest case, bedded salt is undeformed, forming a continuous gently-dipping layer prior to shortening. In this situation, where shortening occurs with no precursor salt structures present, the salt simply acts as a décollement, ‘lubricating’ predominantly linear fold-and-thrust belts above that show extremely low taper angles (e.g. Davis and Engelder, 1985; Letouzey et al., 1995; Morley et al., 2011) (Fig. 1a). Common structural styles observed in such settings are salt-bearing thrusts, box folds, and long-wavelength, broad anticlines separated by narrow, sharp synclines (Fig. 1a). In general, there is little along-strike variability in structural style, aside from those developed due to along-strike variations in the depositional thickness of the salt (e.g. Davis and Engelder, 1985). Contractual provinces in which salt acts primarily as a detachment include the Valley and Ridge Province of the Appalachians (e.g. Frey, 1973), the Betics and Rif (e.g., Flinch and Soto, 2017), the Pyrenees (e.g., Canerot et al., 2005; Roca et al.,

2011; Carlola et al., 2015; Cámara and Flinch, 2017), the Albanides (Velaj et al., 1999; Bega and Soto, 2017), the Carpathians and Balkans (e.g., Georgiev and Tari, 2017), the Jura Mountains and the Alps (e.g., Guellec et al., 1990; Sommaruga et al., 2017; Leitner and Spötl, 2017), the Salt Range (e.g. Grelaud et al., 2002), the Rhodanian Basin (Lickorish and Ford, 1998), the Perdido fold belt in the Northwestern Gulf of Mexico (e.g. Trudgill et al., 1999), and the Northwestern Zagros Mountains (e.g. Sherkati et al., 2006; Dooley et al., 2007).

In the second and third styles, which are less understood, diapirs exist prior to shortening. During shortening, the weak diapirs narrow and rise, whereas the relatively strong surrounding sedimentary rocks remain largely undeformed (e.g. Nilsen et al, 1995; Canerot et al. 2005; Rowan and Vendeville, 2006; Callot et al., 2007; Hudec et al, 2011; Bega and Soto, 2017; Duffy et al, 2017) (Fig 1b). Diapir provinces thus form sensitive barometers to lateral compressive stresses (Roca et al., 2006; Dooley et al., 2009; Hudec et al. 2011; Dooley et al., 2015). The style of shortening in these systems, and the characteristics of the resultant fold-and-thrust belts, depends to a large extent upon the pre-shortening configuration of the diapirs. Structural styles are also more prone to vary along the strike of the resultant fold-and-thrust belt.

In the second style, the focus of this study, isolated stocks or walls are encased in a relatively rigid sediment body (Fig. 2). We term this an *isolated-diapir province*. In the third style, not addressed in this study, isolated minibasins are surrounded by salt walls on all sides; that is, the minibasins are adrift in a ‘sea of salt’. This third style was previously referred to as a *wall and basin* province in Harrison and Jackson (2014) and Kergaravat et al. (2016), but is herein termed an *isolated-minibasin province*. Isolated-diapir and isolated-minibasin provinces shorten differently due to differences in the volume and distribution of mechanically weak salt, as well as differences in the potential lateral mobility of minibasins (Duffy et al., 2017).

Here we focus on thin-skinned shortening of isolated-diapir provinces and on the characteristics of the resultant fold-and-thrust belt. We outline the fundamental mechanical principles that govern how isolated-diapir provinces shorten and use these principles to answer the following questions: i) what structural styles develop as a single isolated diapir shortens? ii) how do isolated diapirs interact with one another during shortening?; iii) how do pre-shortening configuration, roof thickness and shortening magnitude control the structural styles developed during shortening of isolated-diapir provinces?; and iv) how and why do structural styles vary across an array? To answer these questions, we synthesize observations from natural examples and physical models of shortened isolated-diapir provinces in what is, at present, a scattered literature. The physical models are of particular value as key structural styles can be viewed in any orientation, structural styles can be documented through time, and variables such as roof thickness, shortening magnitude and diapir configuration may be modified. Based on our observations we then develop a series of 3-D conceptual models that provide a template for understanding the likely pre-shortening configuration, degree of shortening, and overall tectonic history of isolated-diapir provinces. We provide examples of key features from shortened isolated-diapir provinces such as the Fars Region of the Zagros Mountains in Iran (e.g. Callot et al., 2012) and the Astrid Fold Belt in the Lower Congo Basin of Offshore Gabon (Jackson et al., 2008) before highlighting differences between fold-and thrust belts developed in sedimentary basins with and without precursor salt diapirs.

This study is based on observations from moderate- to mildly-shortened settings and physical models. However, the pre-shortening diapir configurations and structural styles described here may be applicable to earlier stages in highly-shortened orogenic settings where the earlier

structure is hard to decipher. Our work may also help enhance the validity of structural restorations and basin models in salt basins worldwide.

## **2. Mechanical Principles Governing the Styles Developed During Shortening of Isolated Diapirs**

The structural style of a shortened isolated diapir is controlled largely by the difference in the mechanical strength between the relatively weak diapir and strong sedimentary rocks surrounding it (e.g. Nilsen et al, 1995; Roca et al., 2006; Rowan and Vendeville, 2006; Callot et al., 2007; Dooley et al., 2009; 2015). This difference in mechanical strength influences how diapirs shorten in three ways. First, shortening strain is preferentially focused on the diapir rather than the surrounding sedimentary rocks, thus the diapir deforms earlier and to a higher degree than the surrounding sedimentary rocks (e.g. Nilsen et al., 1995). Second, shortening structures nucleate at the diapir and propagate outwards into the surrounding sedimentary rocks (e.g. Callot et al., 2007; 2012; Jackson et al., 2008; Dooley et al 2009; 2015). Third, when the walls of the diapir converge, the roof also shortens (Nilsen et al, 1995; Dooley et al., 2009; 2015).

We first explore how single and geometrically-simple isolated diapirs respond to shortening before exploring the effects of more geometrically-complicated diapirs, diapir arrays, and variable roof thickness. Despite the complexity inherent in some diapir settings, it is critical to note that the three fundamental principles outlined above underpin the processes and structural styles that develop in all shortening scenarios involving isolated diapirs.

## **3. Shortening Style of a Single Isolated Diapir**

Variations in the map-view, profile, size, and orientation with respect to the shortening direction of diapirs means that each salt diapir will respond differently to shortening (e.g. Vendeville and Nilsen, 1995; Callot et al., 2007; Jackson and Hudec, 2017). Irrespective of diapir morphology, the preferential deformation of the salt relative to the surrounding sedimentary rocks leads to the development of generic features that can help determine, to the first order, if a given diapir has been squeezed. These include: i) a narrow or welded-out diapir stem (secondary weld); ii) evidence of diapir rise after the (salt) source layer surrounding the diapir has been depleted; iii) a thick, isopachous, arched sedimentary roof; and iv) shortening structures, that is, folds and thrusts, adjacent to the diapir (e.g. Vendeville and Nilsen, 1995; Gottschalk et al., 2004; Rowan et al., 2004; Roca et al., 2006; Jackson et al., 2008; Dooley et al., 2009; 2015; Jackson and Hudec, 2017). However, to fully recognise the degree of diapir shortening, it is valuable to note the sequence in which map-view structural styles develop as a generic isolated diapir is shortened. For this we assume that the diapir is initially elliptical in map-view here (i.e. a stock), but the generic features described are typical of most common diapir geometries.

The sequence of structures that develop during the shortening of an isolated diapir is strongly conditioned by salt's weakness in combination with strain magnitude. At low strains, far-field hinterland shortening thickens the sediment pile driving pressurised source-layer salt towards the foreland and into the diapir (Dooley et al., 2009; 2015). The mechanical weakness of the salt diapir relative to the stronger surrounding sedimentary rocks means that the diapir flanks begin to converge. As this begins the diapir, in this case a circular stock, narrows and rises, and the roof shortens (Fig. 3a) (Nilsen et al., 1995). This squeezing of the diapir and shortening of the roof occurs well ahead of the advancing thrust-front such that the diapir forms a thrust-front salient (Fig. 3a) (Dooley et al., 2009, 2015). At these low strains, even though the diapir and its

roof have deformed to accommodate some shortening strain, shortening of the surrounding sedimentary rocks is instead accommodated solely by lateral compaction (e.g. Koyi et al., 2004; Dooley et al., 2009).

At intermediate shortening strains, the diapir continues to preferentially accommodate shortening strain relative to the surrounding sedimentary rocks. The salt is significantly pressurised and rises allowing the diapir to narrow in the shortening direction and lengthen normal to the shortening direction (Fig. 3b) (e.g. Nilsen et al., 1995; Callot et al., 2007; Dooley et al., 2009). The key point here is that to maintain kinematic compatibility, thrusts, folds or a combination of both must nucleate at the diapir before propagating out into the adjacent sedimentary rocks (Fig 3b) (Koyi, 1988; Nilsen et al., 1995; Baldschuhn et al., 2001; Rowan et al., 2001; Gottschalk et al., 2004; Letouzey and Sherkati, 2004; Rowan et al., 2004; Callot et al., 2007; Jackson et al., 2008; Fernandez and Kaus, 2014). In particular, faults commonly nucleate on the hinterland side of the diapir and subsequently propagate into the surrounding sedimentary rocks. For these faults, fault portions nearest the diapir will generally be oriented parallel to the shortening direction before curving to strike perpendicular to the shortening direction further away (Fig. 3b) (e.g. Nilsen et al., 1995; Gottschalk et al., 2004; Jackson et al., 2008; Dooley et al., 2015). The slip-vector on the faults thus also changes from strike-slip to dip-slip along the faults. Sub-vertical fault portions adjacent to the diapir that strike parallel to the shortening direction accommodate strike-slip motion (i.e. act as lateral ramps), obliquely-striking fault portions accommodate transpression (i.e. act as oblique ramps), and fault portions further away from the diapirs accommodate reverse fault motion (i.e. act as frontal thrusts) (Fig. 3b). The portions of the faults that strike parallel and obliquely to the shortening direction bound a fault block termed a primary indenter (Fig. 3b) (Dooley et al., 2009; 2015). At intermediate strains the

indenter is a salient in the deformation front that develops as the block in the immediate hinterland of the diapir moves faster towards the foreland than the adjacent strata. The indenter does this because it is moving into the relatively weak diapir and displacing salt (Fig. 3b) (Dooley et al., 2009; 2015).

At high strains, the thrust belt in the sedimentary rocks on either side of the diapir further into the foreland than the diapir, with thrusts converging towards the diapir (Fig. 3c) (Dooley et al., 2015; Jackson and Hudec, 2017). The mechanically weak diapir is partly enveloped within the thrust belt and now forms a re-entrant in the thrust-front (Fig. 3c) (e.g. Dooley et al., 2015). As shortening continues, a series of escape structures develop in the pop-ups flanking the diapir (Fig. 3c) (Dooley et al., 2015). These structures, termed ‘secondary indenters’, may converge on, and constrict the diapir along transpressional faults.

#### **4. Influence of Roof Thickness on Structural Styles Developed During Shortening of an Isolated Diapir**

The classic sequence of structural styles described above commonly occur as a simple diapir shortens, particularly in settings prone to shorten by thrusting. However, differences in diapir roof thickness may complicate the deformation. When a thin-roofed diapir is squeezed, the weak roof is easily deformed, pierced and dismembered by upward flow of salt, and thus salt extrusions and secondary welds are common (e.g. Rowan and Vendeville, 2006; Dooley et al., 2015). In contrast, when a thick-roofed diapir is squeezed, the strong roof is more resistant to deformation and thus will tend to resist major upward flow of salt and piercement (e.g. Rowan and Vendeville, 2006; Dooley et al., 2009). In this case: i) salt extrusions are rare; ii) it is much

more difficult to expel sufficient salt to develop secondary welds; and iii) salt is pumped back down into the source layer (Dooley et al., 2009). We now examine structural styles associated with shortening of thin- and thick-roofed diapirs, respectively.

#### ***4.1. Styles Associated with Shortening of a Thin-Roofed Diapir***

At low strains, as the diapir flanks begin to converge, the diapir narrows and rises. In the presence of a thin, weak roof, the rising salt stretches and uplifts the roof to accommodate a dynamic bulge (Fig. 4) (Dooley et al., 2015). An upturned collar of roof sediments forms as the roof diverts some rising salt towards the diapir periphery to form a peripheral bulge (Dooley et al., 2015). As strain focuses on the diapir and its deformed roof, roof thrusts may form on the foreland or hinterland side of the diapir (Fig. 4a).

At intermediate shortening strains, salt in the diapir is significantly pressurised and the diapir continues to narrow and rise. Once the dynamic bulge and thin roof is arched high enough to surmount the upturned collar, the roof spreads outwards, forming both radial and peripheral graben (Fig. 5) (Davison et al., 2000; Dooley et al., 2015). The salt eventually extrudes through the thin, weakened roof either through the radial and peripheral graben, or across the upturned collar (Figs. 4 and 5). At this time, the thin roof dismembers into a series of rafts that are carried away to the periphery of the sheet before grounding and being engulfed by the flow (Figs. 5 and 6) (e.g. Dooley et al., 2015). Extruded salt typically flows down-dip towards the foreland, but may also flow into any local lows such as the footwall of an adjacent thrust, and highs created by folds and thrusts may channel salt along-strike (Fig. 6) (see Dooley et al., 2015 for details).

At high strains, once the mechanically weak diapir is enveloped within the thrust belt and forms a re-entrant in the thrust front, secondary indenters converge on and constrict the diapir

along transpressional faults (Fig. 3c and 6) (Dooley et al., 2015). As the thin-roof has undergone break-up, salt can easily flow upward and extrude as the diapir narrows (Figs. 4 and 6). This increases the likelihood of opposing diapir flanks touching to form a sub-vertical secondary weld that separates an extruded salt sheet above from a triangular pedestal below (Fig. 4b) (e.g. Nielsen et al., 1995; Koyi, 1998; Fort et al., 2004; Roca et al., 2006; Rowan et al., 2012). If shortening continues after the diapir has pinched shut, the sub-vertical secondary weld stem may be offset by a thrust (Fig. 4c) (Callot et al., 2007; Jackson and Hudec, 2017). Dipping secondary welds may be reactivated as thrusts (e.g. Rowan et al., 1999).

#### ***4.2. Styles Associated with Shortening of a Thick-Roofed Diapir***

Based on the detailed description of how an isolated diapir with a thick-roof accommodates shortening presented by Dooley et al (2009), an isolated thick-roofed diapir shows three differences to a comparable thin-roofed diapir during shortening. First, although the diapir roof arches in both thick- and thin-roof scenarios, in thick-roof examples, the crestal graben that develop typically strike parallel to the shortening direction, whereas in the thin-roof scenario, radial and peripheral graben develop (Withjack and Scheiner, 1982; Dooley et al., 2009, 2015). Second, in the thick-roofed scenario the roof is too strong and cannot break-up and dismember to form roof rafts (Fig. 7) (cf. Dooley et al., 2009, 2015). Third, and perhaps most importantly, where the diapir roof is thick and strong, and thus does not break-up, there is no conduit for pressurized salt to extrude (Fig. 7). Consequently, for the diapir flanks to converge, salt in the diapir is pumped downward as an outward plume that is expelled back into the source layer, providing it is thick enough to accommodate this downward and outward flow (Fig. 7) (Dooley et al., 2009).

251

## 252 **5. Shortening of an Array of Isolated Diapirs**

253 Having described shortening styles associated with *single* isolated diapirs, we now broaden the  
254 scope of our study to describe shortening styles in *arrays* of isolated diapirs so as to explore the  
255 consequences for the evolution of the fold-and-thrust belts. Studies examining shortening styles  
256 in diapir arrays and the implications for fold-and-thrust belts are relatively rare, the work of and  
257 Brun and Fort (2004), Letouzey and Sherkati (2004), Jahani et al. (2009), Callot et al. (2007,  
258 2012), and Fernandez and Kaus (2014) being notable exceptions. During shortening, individual  
259 isolated diapirs within the array will essentially behave like single diapirs described in sections 3  
260 and 4, and following the mechanical principles outlined in section 2. However, numerous  
261 important questions remain to elucidate, including: i) how do diapirs interact and link with one  
262 another?; ii) how does the initial configuration of diapirs influence structural style?; and iii) how  
263 and why do structural styles vary across a diapir array?

264

### 265 ***5.1. How do diapirs interact across a shortened array?***

266 As previously described, diapirs deform more readily than the surrounding sedimentary rocks  
267 under compressional stress. In areas prone to buckling, anticlines typically nucleate at, and  
268 propagate away from, each of the diapirs (e.g. Fernandez and Kaus, 2014). Anticlines develop  
269 rather than synclines as arched (i.e. anticlinal) diapir roofs are amplified by buckling (Callot et  
270 al., 2007, 2012; Jahani et al., 2009; Fernandez and Kaus, 2014; Jackson and Hudec, 2017). In  
271 contrast, where faulting predominates, thrust, transpressional and tear faults (frontal ramps,  
272 oblique ramps and lateral ramps, respectively) generally nucleate at, and propagate outward from

each of the squeezed diapirs (Fig. 8) (Dooley et al., 2009, 2015; Jackson and Hudec, 2017). As shortening strain increases, the faults or folds lengthen, eventually interacting and linking with those from nearby diapirs (Fig. 8b) (Callot et al. 2012; Jackson and Hudec, 2017). A corollary of this is that closely-spaced diapirs will typically link earlier in the shortening history, that is, at lower strains, than widely-spaced diapirs. Mature shortened diapir arrays thus consist of diapirs, or their equivalent welds, that are linked to one another by folds, thrusts or tear faults in the intervening sedimentary rocks (Fig. 8b-c) (Callot et al., 2012).

Settings where a cluster of precursor diapirs are located adjacent to a broad region of flat-lying salt that has no precursor diapirs are also of note. As these settings shorten, each diapir forms a local primary indenter and salient in the deformation front as described previously (e.g. Fig. 3). However, diapir cluster as a whole will form a *composite* primary indenter and deformation front salient relative to the area detached on the unstructured salt. This is due the presence of the mechanically weak salt in the overburden that facilitates a greater rate of propagation of deformation into the foreland in the diapir array than the area detached on unstructured salt.

Overall, these concepts provide a general framework as to how diapirs interact. However, we now consider how the precursor configuration of diapirs controls the geometry, kinematics and orientations of the resultant fold-and-thrust belt (e.g. Callot et al., 2012).

## ***5.2. How does the precursor diapir configuration influence the structural style of fold-and-thrust belts?***

Prior to shortening, an array of isolated diapirs may be configured in a variety of ways, for example they may be: i) aligned perpendicular to the shortening direction; or ii) tangentially- or

obliquely offset with respect to one another both parallel to, and perpendicular to, the shortening direction (Fig. 9). These different configurations control the overall structural styles that develop during shortening (Fig. 10). A common configuration in nature, and thus oft-represented in physical models, involves an array of diapirs that are aligned perpendicular to the shortening direction. In buckling-prone settings if diapir arrays are aligned perpendicular to the shortening direction, anticlines nucleate at the diapirs before propagating away along strike, connecting with folds flanking adjacent diapirs. An anticlinal fold belt develops that is oriented perpendicular to the shortening direction; diapirs are located along the axis of the folds (e.g. Fars Province of the Zagros Mountains in Iran: Letouzey and Sherkati, 2004; Jahani et al., 2009; Callot et al., 2012). Note that an exception occurs when precursor diapirs are closely-spaced in the shortening direction, in this case diapirs may be located in the limbs of folds or in synclines (e.g. Rowan, 2003; Jahani et al., 2009; Callot et al. 2012; Fernandez and Kaus, 2014). A similar process to the development of the anticlinal fold chain occurs in fault-prone settings. In these settings, sub-linear fold and thrust belts develop that strike perpendicular to the shortening direction and which show faults that locally curve in toward the diapirs (Fig. 8) (e.g. Lower Congo Basin, Gabon; Jackson et al., 2008).

Arrays of stocks and walls that are not aligned with one another perpendicular to the shortening direction may have varying degrees of offset with one another both parallel- and perpendicular- to the shortening direction (Fig. 9). In these scenarios, the precise arrangement of the diapirs with respect to one another, along with the roof thickness, will control the type and orientation of structures that develop to connect the diapirs. Where thin-roofed diapirs are tangentially offset from one another, faults nucleate at, and propagate away along-strike from, each of the diapirs (Fig. 10a). The striking feature in this particular configuration is that the

diapirs link to one another via a single tear fault, or series of small tear faults within a narrow strike-slip fault zone, oriented parallel to the shortening direction. In contrast, if the diapir roof is thick, the diapirs may link by the formation of a pop-up structure that is oriented oblique to the shortening direction. Where thin-roofed diapirs are obliquely-offset from one another, the diapirs link to one another via a transpressional pop-up structure oriented oblique to the shortening direction (Fig. 10b). On the other hand, if the roof is thick, faults that propagate away from the diapirs may curve at their tips to link the obliquely-offset diapirs.

A further consideration is the degree of connectivity of the diapirs prior to shortening. In some cases, such as in the sub-canopy system of the northern Gulf of Mexico, the isolated diapirs are connected at depth by a polygonal network of buried salt anticlines or ridges (Fig. 11). These anticlines or ridges radiate and plunge away from each of the diapirs to form an egg-carton-like precursor geometry (Fig. 11) (Rowan and Vendeville, 2006). During shortening, both the diapirs and the deep anticlines or ridges localize the shortening strain. As such, faults and folds nucleate at the diapirs, and propagate away following the axes of the deep anticlines or ridges. The result is a polygonal network of faults and folds in the supra-salt that reflects the map-view pattern of the underlying anticlines or ridges (e.g. Rowan and Vendeville, 2006). It is likely that the more deeply-buried the anticlines or ridges are relative to the isolated diapirs, the lesser the effect they will have upon the final map-view pattern of faults or folds. This type of system, and the map-view geometries developed, differ markedly to the sub-linear fold-and thrust belts developed during shortening of provinces with completely unconnected precursor isolated diapirs.

### ***5.3. How and why do structural styles vary across a diapir array?***

There are two fundamental reasons as to why structural styles vary across a diapir array. First, shortening strains must propagate across the array in the dip direction, so some diapirs within the array may be more strained than others. In systems driven by plate tectonics (e.g. Fars Province of the Zagros Mountains in Iran, Betic foreland, Pyrenean foreland), shortening strains propagate from the hinterland toward the foreland, thus diapirs located closer to the hinterland will be shortened earlier and to a higher degree than those located towards the foreland. In contrast, in gravity-driven slope systems, strain propagation is much more variable. Important factors include the presence or absence of a buttress, critical taper geometry, salt thickness, the location of the salt pinchout, the presence of hinges in the detachment surface, the location of the base of slope, overburden strength, and strain rate (e.g. Letouzey et al., 1995; Dooley et al., 2007, 2013; Jackson et al., 2008; Morley et al., 2011).

The second reason is that diapirs within an array may show variations in cross-sectional profile, map-view geometry, size, and orientation of diapirs with respect to the shortening direction. Furthermore, there may also be spatial variations in the style and degree in which pre-existing faults influence the sedimentary rocks surrounding the diapirs. These types of variations result in the development of different structural styles during shortening (Roca et al., 2006; Callot et al., 2007; Jackson and Hudec, 2017). A complete discussion of these variables is beyond the scope of this study, however, we comment on two of the most important factors.

First, diapirs with different cross-sectional profiles respond to shortening in varying ways. For example, initially narrow diapirs rise higher and faster than wide diapirs during shortening. Higher and faster rising salt results in more steeply-arched roofs above initially narrow diapirs (Fig. 12a) (Nilsen et al., 1995). Variations in the angle of the salt-sediment interface at the diapir flanks may also influence structural style development. Low-angle salt-

sediment interfaces can act as thrust ramps (Fig. 12b) (Callot et al., 2007). In contrast, steep salt-sediment interfaces are not favourably oriented for thrusting. Short-cut thrusts may thus form at or near the base of the diapir, passively transporting a large part of the diapir in the developing fold in the thrust hanging-wall (Fig. 12b) (see Callot et al., 2007 for further details).

Second, there may be a range of map-view diapir geometries within the precursor diapir array, in particular salt walls may have different orientations with respect to the shortening direction (Figs. 12c and d). For example, some walls may have their long axis oriented perpendicular to the shortening direction (perpendicular walls) whereas other walls may have their long axis parallel or oblique to the shortening direction (parallel walls and oblique walls, respectively). Each of these will respond differently to shortening (Figs. 12c-d and 13). Perpendicular walls are the easiest to weld shut because they maximize the volume of expelled salt for an increment of shortening (Fig. 12d). However, the strength of sedimentary rocks around the ends of the wall means that the centre of the wall may be squeezed more than the ends. The tips may thus resist welding leaving two remnant diapirs connected by a vertical weld (e.g. La Popa weld in Rowan and Vendeville, 2006) (Fig. 12c). Parallel walls extrude much less than perpendicular walls given the same amount of shortening and require therefore more shortening to close (Fig. 12d). Structural styles become more complex with oblique walls and can vary according to the degree obliquity to the shortening direction (Fig. 13). Oblique walls experience transpressional stresses and hence form uplifts bounded by oblique-slip reverse faults. Furthermore, the ends of oblique walls, and any faults emanating from their tips, curve progressively to align with regionally-oriented thrust faults; thus oblique walls commonly display sigmoidal map-view geometries (e.g. Gottschalk et al., 2004; Callot et al., 2012) (Fig. 13).

387

## 388 **6. Conceptual Models of Shortening in Isolated-Diapir Provinces**

389 Based on the preceding observations from natural and physically-modelled systems, we present a  
390 series of conceptual models that synthesise how roof thickness, diapir configuration, and  
391 shortening magnitude influence structural styles developed during shortening of isolated-diapir  
392 arrays (Figs. 14 and 15). The pre-shortening configuration of the models is shown in Figure 2.  
393 The models assume that shortening is thin-skinned and propagates from the hinterland on the  
394 right, to the foreland on the left. Comparing structural styles in the foreland and hinterland we  
395 thus capture temporal evolution at increasing strain. We also assume no syn-shortening  
396 sedimentation, erosion, or variation in shortening rates. We vary roof thickness and strain  
397 magnitude.

398

### 399 ***6.1. Thin-Roofed Scenarios***

400 At low strains (Fig. 14a), diapir roofs in the foreland are captured early in the process of break-  
401 up, with arching and crestal faulting being dominant. In contrast, diapirs roofs located towards  
402 the hinterland are more highly-strained, with overturned flaps, extrusive salt sheets and roof rafts  
403 being common. In a similar vein, less-strained diapirs toward the foreland remain open in section  
404 view as salt continues to flow into the diapir, whereas the flanks of more highly-strained diapirs  
405 toward the hinterland are welded shut at the waist. The connectivity of tear faults,  
406 transpressional, and thrust faults emanating from the diapirs is low. The diapir array is not  
407 connected by faults and swathes of the sedimentary rocks between the diapirs are largely  
408 undeformed.

At high strains, all diapirs in the array, even those located toward the foreland, experience strong deformation (Fig. 14b). Diapirs tend to be welded shut, with some secondary welds reactivated as thrusts, or, in the case of very high strains, offset by short-cut thrusts. The convergence of diapir flanks that is required to weld the diapirs is facilitated by break-up of the weak diapir roofs and subsequent extrusion of salt sheets. If the diapirs are relatively closely-spaced, the salt sheets may coalesce to form a canopy.

There are several key differences between the high- and low-strain scenarios (cf. Figs. 14a and b). First, at high strains, the diapirs form local re-entrants in the deformation front rather than the salients observed at low strains. Second, at high strains, the faults and folds emanating from each diapir have lengthened and linked with those from adjacent diapirs. Thrust faults and folds link diapirs that are broadly along-strike (or obliquely-offset) from each other, whereas tear faults link diapirs that are tangentially offset from one another parallel to the shortening direction. Third, at high strains, once the diapirs are welded shut, they eventually lock up and deformation migrates to any remaining open diapirs further toward the foreland.

## **6.2. Thick-Roofed Scenarios**

At relatively low strains, thick-roofed settings show some similarities in structural style to mildly-strained thin-roofed settings (cf. Figs 14a and 15a). Diapir roofs toward the foreland are only gently arched, whereas diapir roofs towards the hinterland display more faulting and folding. Second, faults and folds remain unlinked and the diapir network is poorly connected. The major differences between thick-roofed and thin-roofed diapir arrays at low strains are that thick-roofed diapirs are much more likely to remain open in cross-section and much less likely to

extrude salt. These differences are a result of the thick and strong diapir roofs that do not easily deform to facilitate diapir flank convergence or break-up to permit salt extrusion.

In highly-strained settings, diapirs are to some extent connected to other diapirs by faults, although the degree of connectivity is not as high as in the thin-roofed scenario (*cf.* Figs 14b and 15b). There are also some key differences. Most importantly, the roofs are too strong to break-up and provide conduits for salt extrusion, so little or no salt is observed at surface. The inability of salt to extrude in thick-roofed settings means that diapirs are more difficult to weld, since there is no easy exit for displaced salt. Some displaced salt forms remnant bulbs at shallow levels and more may be pumped downwards as outward plumes into the source layer. These outward plumes thicken the source layer and hydraulically lift fault blocks, perhaps facilitated by a distal thrust at the edge of salt (Dooley et al., 2009). Pumping salt down into the source layer and lifting up sediments requires much more force than simply having salt rise and extrude at the surface as occurs in thin-roofed scenarios, and requires much higher salt pressures. Thus, not all the salt may be expelled from the diapirs, and some diapirs may just be narrowed rather than welded.

## **7. The Influence of Precursor Isolated Diapirs on the Styles of Fold-and-Thrust Belts**

If sedimentary basins do not contain diapirs prior to thin-skinned shortening, the map-view configurations of the fold-and-thrust belts that develop are relatively simple (Fig. 16). Fold and thrust traces are sub-linear to curvilinear in form, are regularly-spaced across-strike, and are

commonly continuous over lengths of 100 km or more with little variation in structural style. Deformation fronts are broadly linear and continuous along-strike. In contrast, when sedimentary basins containing precursor isolated diapirs are shortened the fold-and-thrust belts become much more complex (Figs. 14 and 15). Many of these key styles are expressed in the Fars Region of the Zagros Mountains in Iran, an area that contained isolated diapirs prior to Neogene shortening (Fig. 17a) (Letouzey and Sherkati, 2004; Callot et al. 2007; 2012; Jahani et al., 2009). Although structures define a fold-and-thrust belt aligned broadly perpendicular to the shortening direction as in the non-diapiric settings in Figure 16, there are also three key differences to those settings. First, fold axes are much shorter (20-80 km) than those seen for example in the Canadian Rockies and the Appalachians ( $>>100$  km) (e.g. Bally et al., 1966; Frey, 1973; Davis and Engelder, 1985). Second, a large number of salt extrusions are present, marking the locations of the pre-existing diapirs (Callot et al., 2007). Third, the diapirs are connected to one another by the network of fold and thrusts, resulting in local deviations in the trends of these structures in the fold-and-thrust belt (Fig. 17a). This configuration is also expressed, albeit at a smaller scale, in the Astrid Fold Belt, Lower Congo Basin, offshore Gabon (Jackson et al., 2008) (Fig. 17b). Overall, this process of fold and fault nucleation at squeezed diapirs and subsequent propagation and linkage of these structures to form a connected fault/fold network is fundamental to the evolution of shortened isolated-diapir provinces (Figs. 8, 10, 14, 15).

As shown here, salt provinces may differ in structural style due to variations in degree of shortening and in pre-shortening salt configuration. An entirely different style of salt-involved shortening occurs where pre-shortening minibasins lie adrift in a sea of salt, that is, they are surrounded by salt walls on all sides (*isolated-minibasin provinces*). If the relatively modest

amounts of salt present in isolated-diapirs cause such major changes in structural style, what happens when there is an order of magnitude more salt (e.g. Duffy et al., 2017)? An analysis of these systems will form the basis of a future study.

## 8. Conclusions

- Shortening styles in salt basins containing diapirs depend largely upon the pre-shortening configuration of the diapirs. We recognize two end-member pre-shortening diapir configurations. In the first, isolated diapirs are encased in a relatively rigid sediment body (*isolated-diapir provinces*). In the second, isolated minibasins are surrounded by salt walls and the minibasins are effectively adrift within a ‘sea of salt’ (*isolated-minibasin provinces*).
- This study examined structural styles associated thin-skinned shortening of isolated-diapir provinces. We found that even though isolated-diapirs form volumetrically minor components of sedimentary basins, they have a disproportionately large influence on structural style due to the relative weakness of rock salt and its ability to localize strain.
- The structural styles developed during shortening of isolated-diapir provinces are governed to a large extent by three mechanical principles. First, diapirs shorten prior to surrounding sedimentary rocks due to their relative weakness. Second, diapirs nucleate folds and faults that propagate out into the surrounding sedimentary rocks. Third, as

diapirs are squeezed, the roof must also shorten; extrusive salt sheets are expelled through thin roofs, whereas thicker roofs resist piercement but may still be faulted and folded.

- In shortened isolated-diapir arrays, faults and folds nucleate at, and propagate away from individual diapirs. These folds and faults link up with structures from adjacent diapirs so that diapirs are all connected. However, the precise configuration of the diapirs with respect to one another, along with roof thickness, will control the style and orientation of structures that connect the diapirs.
- First-order controls on the structural styles in shortened isolated-diapir provinces are pre-shortening configuration and degree of connectivity of diapirs, strain magnitude and diapir roof thickness. Second order controls on structural style development include: initial diapir cross-sectional profiles, map-view geometry of diapirs, diapir size, and diapir orientation with respect to the shortening direction.
- Structural styles of fold-and-thrust belts developed in basins with isolated-diapirs developed prior to shortening (e.g. Fars Region of the Zagros Mountains and the Astrid Fold Belt in the Lower Congo Basin of Offshore Gabon) exhibit more complex geometries and greater spatial variability in structural styles than fold-and-thrust belts developed above a simple décollement (e.g. Southern Canadian Rockies and the Appalachian Plateau, USA).

## **9. Acknowledgements**

We would like to thank Nancy Cottington for figure drafting, particularly the 3D conceptual models and Frank Peel, Gillian Apps, and Maggie Curry for discussions that helped refine this work. The project was funded by the Applied Geodynamics Laboratory (AGL) Industrial Associates program, comprising the following companies: Anadarko, Aramco Services, BHP Billiton, BP, CGG, Chevron, Condor, EcoPetrol, EMGS, ENI, ExxonMobil, Hess, Ion-GXT, Midland Valley, Murphy, Nexen USA, Noble, Petrobras, Petronas, PGS, Repsol, Rockfield, Shell, Spectrum, Statoil, Stone Energy, TGS, Total, WesternGeco, and Woodside (<http://www.beg.utexas.edu/agl/sponsors>). The authors received additional support from the Jackson School of Geosciences, The University of Texas at Austin. The stay of Juan I. Soto at the Bureau of Economic Geology has been funded by a Salvador de Madariaga fellowship of the Ministerio de Educación, Cultura y Deporte, Spain.

## 10. Figure Captions

**Fig. 1.** Style of shortening depends on the relative thicknesses of overburden and salt along with whether or not diapirs were present prior to the onset of shortening. These forward models maintain salt area through time (after Hudec and Jackson 2007).

**Fig. 2.** Schematic figure showing a pre-shortening configuration typical of an ‘isolated-diapir province’ with discrete salt stocks and walls. Sequences coloured in blue represent sediment deposited during the growth of the diapirs and prior to the deposition of the roof (green units). Dark green unit, if imagined that it covers across the entire area of model, represents what we term a thin roof. Light green unit, if imagined that it covers across the entire area of model, represents what we term a thick roof.

**Fig. 3.** Schematic structural evolution of a shortened isolated diapir (in this case, a stock) in map view. a) initial squeezing and associated salt rise in the diapir in advance of the deformation front; b) fault-bounded primary indenter block moves into a yielding diapir; the diapir forms a salient in the deformation front; c) diapir changes from a salient in the deformation front to a re-entrant; secondary indenters converge on and constrict the diapir. Based on physical models in Dooley et al. (2015).

**Fig. 4.** Series of cross-sections through a thin-roofed isolated diapir at increasing degrees of shortening. Cross-sections are oriented parallel to the shortening direction. a) at low strain the squeezed diapir remains open but the roof is arched; b) at intermediate strain the diapir is squeezed shut to form a vertical secondary weld and the salt has extruded through the thin roof leaving an overturned flap; and c) at high

strains the vertical secondary weld has been offset by a new shortcut thrust (note that in some cases, the secondary weld can be reactivated as a thrust weld, particularly if the initial weld was dipping).

**Fig. 5.** Roof break-up sequence of an isolated thin-roofed diapir (stock) at increasing degrees of shortening strain (after Dooley et al., 2015). a) radial and peripheral grabens form in the uplifting stretched roof; b) as shortening increases, the pressurised salt continues to rise, breaking through the weak radial and peripheral grabens in the roof; c) salt lobes extrude through the weak points in the roof before coalescing. R1 to R5 refer to individual portions of the roof or rafts.

**Fig. 6.** Overhead views of a physical model of a single isolated diapir (a stock) with a thin roof at various degrees of shortening strain. a) at very low strain the roof above the squeezed diapir is uplifted and radial and peripheral graben form; diapir forms a salient in the deformation front; b) as strain increases the diapir roof breaks up and the salt extrudes; c) at intermediate shortening strains salt continues to extrude, flowing towards the foreland (left); faults nucleate on the hinterland side (right) of the squeezed stock and propagate outwards to define a primary indenter block that drives into the diapir; d) at high shortening strains there is massive salt extrusion, secondary indenters and pop-ups developed adjacent to the diapir, which forms a re-entrant in the deformation front.

**Fig. 7.** Overhead and cross-section views showing key structural styles associated with shortening of single isolated diapir with a thick roof (modified from Dooley et al., 2009). Shortening direction in all models is from the right to left. a) Overhead view at mild shortening strains (7.5 cm) and b) cross-section through a) along line of section x-x'. Note how the inward plume of salt inflates the diapir. c) Overhead view at intermediate shortening strains (15 cm) and d) cross-section through c) along line of section y-y'. e) Overhead view at high shortening strains (30 cm) and f) cross-section through e) along line of section z-z'. Note how salt is not extruded at the surface and how salt is pumped out of the diapir and into the source layer via a major outward plume. e) is at the same scale as a) and c) but the field of view has shifted to show the basin-edge thrust.

**Fig. 8.** Overhead views of a physical model of an array of diapirs (stocks) that are aligned perpendicular to the shortening direction (each diapir had a thick roof). Blue circles show the initial location of the diapirs. At low shortening strains (a) minimal deformation is observed. At moderate shortening strains (b) diapirs preferentially localise shortening strain so faults and folds nucleate at diapirs and propagate out into the surrounding sedimentary rocks. At strong degrees of shortening (c) the faults and folds have propagated laterally such that they now link the diapirs perpendicular to the shortening direction.

**Fig. 9.** Sketch showing in map-views of different diapir (stock) configurations: a) diapirs aligned perpendicular to the shortening direction; b) tangentially-offset diapirs (tangent parallel to shortening direction) and c) obliquely-offset diapirs. Diapirs are pink. White arrow shows the shortening direction.

**Fig. 10.** Overhead views showing the result of shortening two thin-roofed isolated diapirs (stocks). The configuration of the diapirs prior to shortening determines the style in which diapirs connect during shortening. a) tangentially-offset salt stocks are connected by tear faults. b) obliquely-offset diapirs are connected by a transpressional pop-up structure.

**Fig. 11.** Map showing portion of the present-day sub-canopy system of the northern Gulf of Mexico where isolated diapirs (diapir roots shown in red; grey if inferred) are connected at depth by buried anticlines or ridges of salt (pink). Black dashed lines are outlines of where shallow salt extruded from the diapir roots. Map of Miocene structural elements are overlain: green lines show normal faults that record extension and/or salt withdrawal; red lines indicate areas of shortening (e.g. folds, thrusts, and squeezed diapirs); and blue lines indicate areas with a likely predominance of strike-slip deformation. The black arrows indicate the shortening direction. After Rowan and Vendeville (2006).

**Fig. 12.** Schematic diagrams showing the influence of the initial cross-sectional profile (a and b) and the map-view geometry (c and d) of the precursor diapir on the structural style developed during shortening. a) initially narrow diapirs rise more than wide diapirs (from Nilsen et al., 1995); b) influence of cover thickness and angle of the salt-sediment interface on the diapir flanks upon structural style developed during shortening (Callot et al., 2007); c) conceptual model of a salt wall that is oriented perpendicular to the shortening direction. The strength of rocks around the wall tips mean it is harder to squeeze the tips of the wall than the ends. When the wall preferentially welds in the centre, leaving two remnant diapirs at the ends ('Q-tips') that are connected by a secondary weld (Rowan and Vendeville, 2006); d) differences in how a perpendicular wall (wall with long axis oriented perpendicular to the shortening direction) and parallel wall (wall with long axis oriented parallel to the shortening direction) respond to incremental shortening (stage 1 is the lowest strain and stage 3 is the highest strain). A-A' and B-B' are schematic cross-sections through the perpendicular wall before and after shortening, respectively. C-C' and D-D' show schematic cross-sections through the parallel wall before and after shortening, respectively. Walls in d) are all assumed to have the same area and volume prior to the shortening.

**Fig. 13.** Overhead views (a and b) and oblique view (c) of a physical model that involved a series of elongate, thin-roofed salt walls with the long axes oriented parallel to, perpendicular to, and at various degrees of obliquity to the shortening direction. Walls A, B, C are broadly aligned with one another as are walls 1, 2, 3 and 4. a) elevation map of the top model surface at mild shortening showing walls oriented oblique to the shortening direction (2, 3, A to C) are squeezed in the foreland (left) of the regional deformation front; obliquely-oriented walls experience transpression and crestal faults developed in the roofs of walls develop in transtension (walls B and C). b) view at intermediate shortening showing extrusion of salt from the walls; c) elevation map showing how the ends of the oblique walls B and C have curved to strike perpendicular to the shortening direction such that the walls display sigmoidal geometries in map-view.

**Fig. 14.** 3D conceptual block models showing the evolution of structural styles at a) at low strain, and b) at high strain during the shortening of a province of isolated *thin-roofed* diapirs. Same colour legend as in Fig. 2.

**Fig. 15.** 3D conceptual block models showing the evolution of structural styles at a) at low strain, and b) at high strain during the shortening of a province of isolated *thick-roofed* diapirs. Same colour legend as in Fig. 2.

**Fig. 16.** Map-view of key structural elements of fold-and-thrust belts that developed without diapirs present prior to shortening: a) a fold-and-thrust belt developed in the absence of a salt decollement in the Southern Canadian Rockies (Bally et al., 1966); and b) a fold-and-thrust belt developed above a salt decollement in the Appalachian Plateau, USA (after Frey, 1973; Chen, 1977; Mesolella, 1978; Davis and Engelder, 1985). Both a) and b) shown at same scale. Note how fault traces and fold axes extend continuously for over 100 km without a significant change in strike and vergence.

**Fig. 17.** a) Map-view of key structural elements of the Fars Province of the Zagros fold-and-thrust belt in the mountains of Iran; isolated-diapirs were present prior to the onset of shortening (modified from Callot et al. 2012 that was compiled from a geological map of the National Iranian Oil Company). Fold axes are not as long as the fault traces in Fig 16, folds largely appearing to connect salt extrusions. b) Map-view taken from Jackson et al. (2008) from the Astrid Fold Belt in the Lower Congo Basin (offshore Gabon) showing a series of allochthonous sheets (proxies for the locations of isolated diapirs) connected by thrust faults and tear faults. Thrust faults typically strike perpendicular to the shortening direction.
