### 10 **Abstract**

11 We present the Lunar Ribus Database, a global catalogue of lunar summits with topographic  
12 prominence  $\geq 1$  km derived from the highest-resolution global and regional digital elevation  
13 models currently available. Each summit in the catalogue is reported with summit and key col  
14 elevations relative to the global minimum, prominence, key col elevation, and geographic  
15 coordinates of both summit and key col. Prominence was computed using the divide-tree  
16 algorithm of Andrew Kirmse (*mountains*).

17 Summits with prominence  $\geq 1$  km, called Ribus, provide a formal measure of morphometric  
18 independence. By linking each summit to its key col, the Lunar Ribus Database establishes a  
19 globally consistent hierarchy of kilometre-scale positive-relief landforms on the Moon. This  
20 framework enables terrain segmentation, analysis of impact- and volcanism-related edifices, and  
21 comparative prominence-based morphometry across planetary bodies.

## 22 **1. Introduction**

23 Topographic prominence provides a parameter-free measure of morphometric independence.  
24 Unlike height above local terrain or break-in-slope detection methods, prominence is defined  
25 solely by the geometry of the digital elevation model and the connectivity of the surface through  
26 its lowest linking saddles.

27 Because it captures the hierarchical structure of relief directly from topography, this metric  
28 has proven valuable for quantifying and characterising landforms across a range of settings. For  
29 example, the United States Geological Survey has applied prominence-based methods to convert  
30 terrestrial summit features from point representations in the Geographic Names Information  
31 System into spatially bounded landforms (Sinha & Arundel, 2020). Its use in planetary  
32 geomorphology includes basin-ring reconstruction on the Moon (Bailey et al., 2020), vent  
33 identification on the Moon (Cañón-Tapia & Jacobo-Bojorquez, 2022), volcanic edifice  
34 characterisation on Mars (Richardson et al., 2021), and segmentation of highland terrain on  
35 Venus (Kiefer et al., 1991).

36 However, such applications have been limited to regional investigations or to specific classes  
37 of landforms. To our knowledge, no globally consistent inventory of prominent summits has  
38 been compiled for any planetary body other than Earth.

39 Here we present a global catalogue of lunar positive-relief features with topographic  
40 prominence  $\geq 1$  km derived from modern digital elevation models. Landforms exceeding this  
41 threshold correspond to the “sub-Ultra” prominence class discussed by Walsh et al. (2022) in  
42 their analysis of South Pole-Aitken basin massifs.

43 In this work, lunar summits with prominence  $\geq 1$  km are referred to as Ribu (singular) and  
44 Ribus (plural), from the Indonesian and Malay word *ribu* meaning “thousand”. The informal  
45 designation “sub-Ultra” for summits of this prominence range has not been widely adopted in the  
46 literature. The term Ribu is therefore used here as a concise label for kilometre-prominence  
47 summits and is applied consistently across a growing set of planetary Ribus catalogues currently  
48 under development (World Ribus Project, 2026).

## 49 **2. Topographic Data Sources**

50 Elevations for the Lunar Ribus Database (Academic Release; hereafter “Lunar Ribus  
51 Database”) were derived from a hierarchy of lunar digital elevation models, selecting the  
52 highest-resolution dataset available at each location.

53 Where available, NAC stereo DEMs (2-5 m/pixel) were used; these occur as localised  
54 regional products derived from imaging by the Lunar Reconnaissance Orbiter Narrow Angle  
55 Camera (Robinson et al., 2010).

56 For locations poleward of  $60^\circ$  latitude, elevations were taken from a polar DEM derived from  
57 the Lunar Orbiter Laser Altimeter (LOLA; Smith et al., 2010). LOLA altimetry has been  
58 compiled into global grids at multiple resolutions (Planetary Data System, 2026); the DEM used  
59 here has a resolution of  $\sim 60\text{m}/\text{pixel}$ . In these products, data gaps are interpolated using splines  
60 under tension (Smith and Wessel, 1990), which suppress unrealistic topographic artifacts in  
61 sparsely sampled regions while preserving the large-scale structure of the surface.  
62 Within  $\pm 60^\circ$  latitude, elevations were obtained from the SLDEM2015 global DEM (Barker et al.,  
63 2016). This model integrates LOLA altimetry with parallax-derived topography from the  
64 SELENE Terrain Camera (TC), using TC stereo data to correct geolocation errors in LOLA and  
65 to replace interpolated regions with measured topography. The resulting DEM preserves the  
66  $\sim 60\text{m}/\text{pixel}$  resolution of the LOLA grid, with the higher-resolution TC imagery downsampled to  
67 match the global topographic scale (Fernandes and Mosegaard, 2022).

68 Elevations are referenced to the lowest resolved natural surface point on the Moon rather  
69 than to an adopted mean planetary radius. This ties the vertical datum directly to an observed  
70 surface location rather than a geometric reference sphere and avoids dependence on externally  
71 adopted lunar radii. Summit elevations, key col elevations, and prominences are therefore  
72 expressed within a consistent geometric framework defined by the topographic datasets used in  
73 the analysis.

74 All feature coordinates are expressed in planetocentric latitude and longitude, consistent with  
75 the source DEMs. Longitudes have been normalised to the  $-180^\circ$  to  $+180^\circ$  convention, with  
76 negative values indicating west and positive values east.

### 77 **3. Methods**

78 Prominence was calculated using the C++ divide-tree algorithm developed by Andrew  
79 Kirmse (*mountains*), which implements a global saddle-based prominence computation derived  
80 from the framework used in WinProm (Earl, 2012). The method treats the digital elevation model  
81 as a continuous surface and derives summit-saddle relationships from the connectivity of the  
82 terrain.

83 The procedure consists of the following steps:

#### 84 **3.1. Summit detection**

85 Summits are identified as local maxima surrounded by lower terrain, independent of the  
86 magnitude of the surrounding elevation difference. Each such maximum represents a candidate  
87 summit.

#### 88 **3.2. Saddle detection**

89 Saddles are identified as locations surrounded by alternating higher and lower terrain, with at  
90 least two higher and two lower neighbouring regions. These points represent the lowest passes  
91 linking adjacent summit domains.

### 92 **3.3. Divide-tree construction**

93 For each saddle, the algorithm follows the direction of steepest ascent from the saddle into  
94 each adjacent higher region until a summit is reached. These saddle-to-summit connections form  
95 a graph linking summits through their intervening passes. If closed loops arise within this graph,  
96 the lowest saddle within the loop and its associated connections are removed, ensuring that the  
97 resulting structure forms a hierarchical divide tree.

### 98 **3.4. Key col identification**

99 From each summit, the divide tree is traversed toward higher summits. The lowest saddle  
100 encountered along such a path represents a candidate key col. When multiple paths to higher  
101 summits exist, several candidate saddles may be identified; the highest of these candidates  
102 defines the summit's true key col.

103 On Earth, the key col of the planet's highest summit is implicitly sea level, providing a  
104 natural external reference. In contrast, a closed surface without oceans, such as the Moon, has no  
105 such reference level, and the highest summit has no higher neighbour from which a key col can  
106 be derived. To maintain a finite and internally consistent prominence hierarchy, we adopt the  
107 convention that the Moon's highest summit and the second most prominent summit share the  
108 same key col. This convention follows directly from the divide-tree interpretation of prominence  
109 and preserves the mathematical structure of the hierarchy.

### 110 **3.5. Prominence computation**

111 Topographic prominence is calculated as the elevation difference between a summit and its  
112 key col.

### 113 **3.6. Summit selection**

114 Summits are retained in the final catalogue if their computed prominence exceeds the  
115 adopted threshold.

#### 116 *3.6.1. Prominence threshold*

117 A minimum prominence threshold of  $P \geq 1$  km was adopted for summit selection. This value  
118 was guided by a combination of geomorphological and practical considerations, as follows:

- 119 • Noise suppression: High-frequency lunar topographic roughness produces landforms with  
120 several hundred metres to  $\sim 1$  km of relief across degraded crater rims, ejecta hummocks,  
121 and overlapping impact structures. Including these abundant small-scale landforms in a  
122 morphometric inventory can obscure morphometrically independent landforms (Walsh et  
123 al., 2023).
- 124 • Structural significance: Features with  $P \geq 1$  km correspond to mechanically coherent  
125 morphologic units such as massifs, well-developed central peaks, and basin-ring  
126 elements.
- 127 • Dataset tractability: The 1 km threshold yields 3670 qualifying summits - sufficient to  
128 capture global morphostructural patterns while remaining computationally and  
129 analytically manageable. Lower thresholds would significantly increase the catalogue  
130 size.

### 131 3.6.2. Initial screening threshold

132 During the initial analysis a provisional prominence threshold of  $P \geq 900$  m was used as a  
133 screening step. This allowed candidate features close to the kilometre-prominence threshold to be  
134 retained while elevations were cross-checked across multiple digital elevation models.  
135 Differences in DEM resolution, interpolation or local data coverage can shift computed  
136 prominences by several tens of metres. Including features slightly below the final cutoff ensured  
137 that summits potentially exceeding  $P \geq 1$  km in higher-resolution or alternative datasets were  
138 examined during validation. The final catalogue retains only those summits confirmed to exceed  
139 1 km prominence after this verification process.

### 140 3.7. Naming of features

141 Lunar features officially named by the International Astronomical Union (IAU) are recorded  
142 in uppercase. Summits in the catalogue lacking an official name have been assigned provisional  
143 lowercase names, following a structured convention. In most cases, unnamed summits are  
144 associated with the nearest officially named lunar feature, typically an impact crater. Individual  
145 summits are distinguished using Greek-letter suffixes, ordered by prominence. The use of Greek  
146 letters follows lunar cartography tradition, where they have historically been used to label  
147 subsidiary features around named craters. Where a summit represents a clearly distinct  
148 morphologic unit, such as a central peak or massif within a crater, a Mons prefix may be used. In  
149 a small number of cases, identifiers already used informally in astronomical literature or  
150 mapping resources are adopted where these can be applied unambiguously.

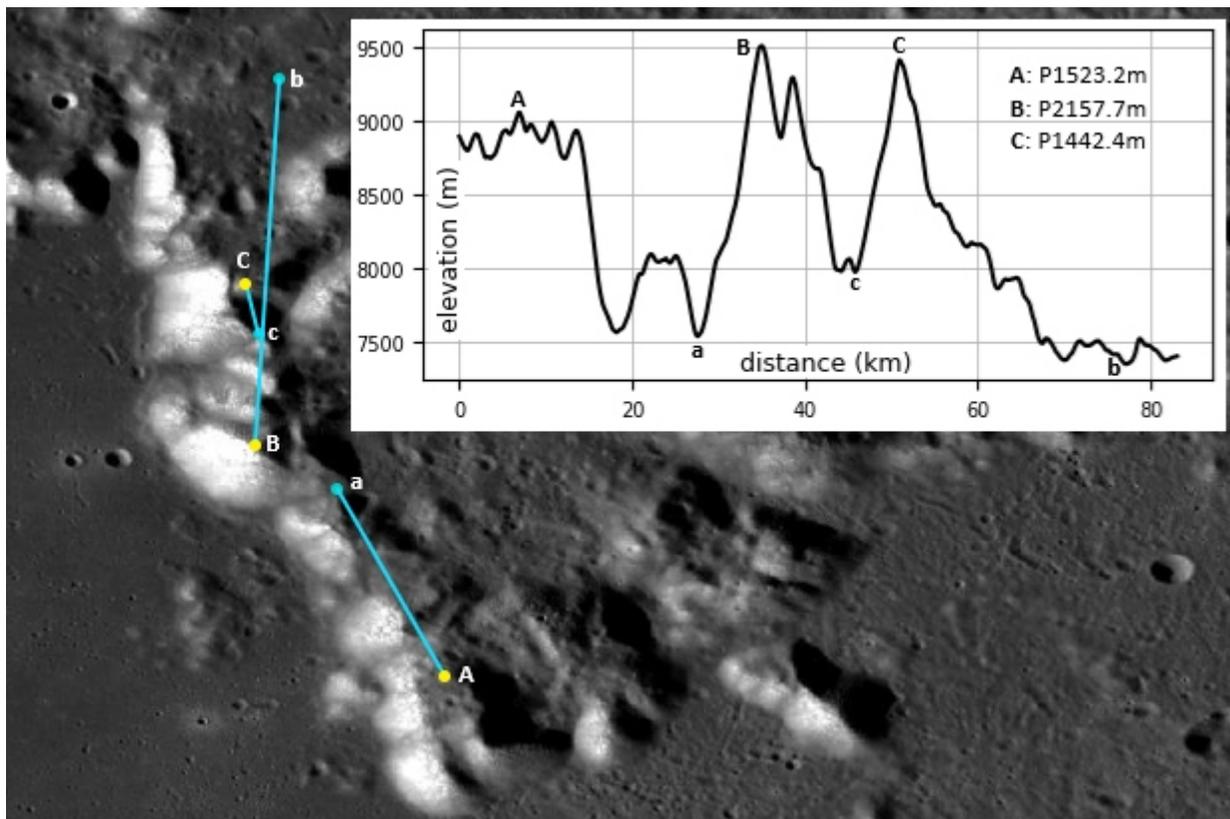

151 Each feature is also assigned a unique catalogue identifier consisting of the prefix L (for  
152 *Luna*/ lunar) followed by four digits (e.g., L1234). These identifiers provide a stable reference

153 for catalogue records independent of provisional naming. The provisional names and identifiers  
 154 are intended solely for use within the catalogue and do not constitute formal nomenclature.

### 155 3.8. Geospatial visualisation

156 To show the geospatial structure of the catalogue and the summit-key col relationships that  
 157 define prominence, the catalogue was converted to GeoJSON format and visualised in Lunar  
 158 Quickmap (NASA et al., 2026), as shown in Figures 1-3.

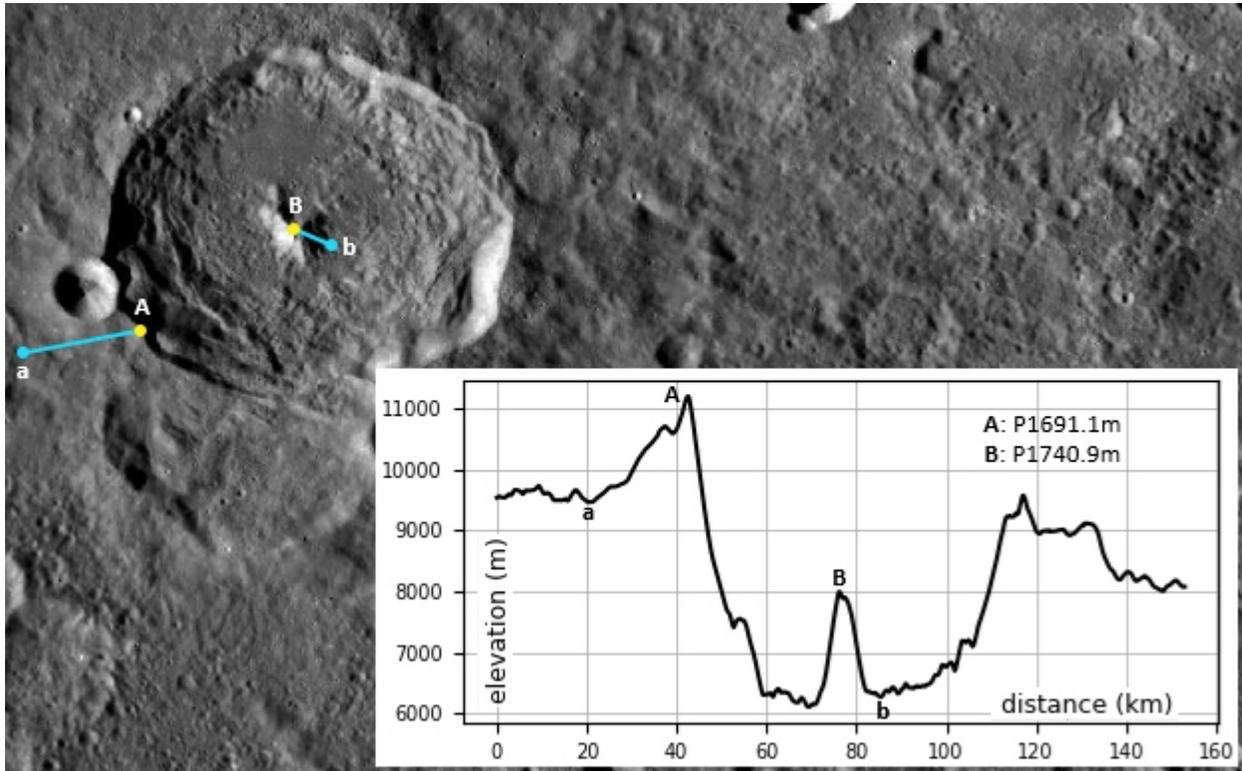

159 The top panel of Figure 1 shows a lunar mountain-range that serves as a real-world  
 160 counterpart to the prominence relationships depicted in Sinha & Arundel (2020).

161 **Figure 1.** Lunar Ribus Database displayed as a GeoJSON layer in Lunar Quickmap. Yellow  
 162 points denote summits, blue points denote key cols, and blue line segments connect each summit  
 163 to its corresponding key col. Seen here is an enlarged view of the southern tip of MONTES  
 164 ALPES. Labeled features are (A) PROMONTORIUM AGASSIZ, (B) PROMONTORIUM  
 165 DEVILLE, and (C) Cassini P Alpha. The inset shows an elevation profile along a multi-segment  
 166 transect connecting each summit and its associated key col, and displays the prominence of each  
 167 summit.

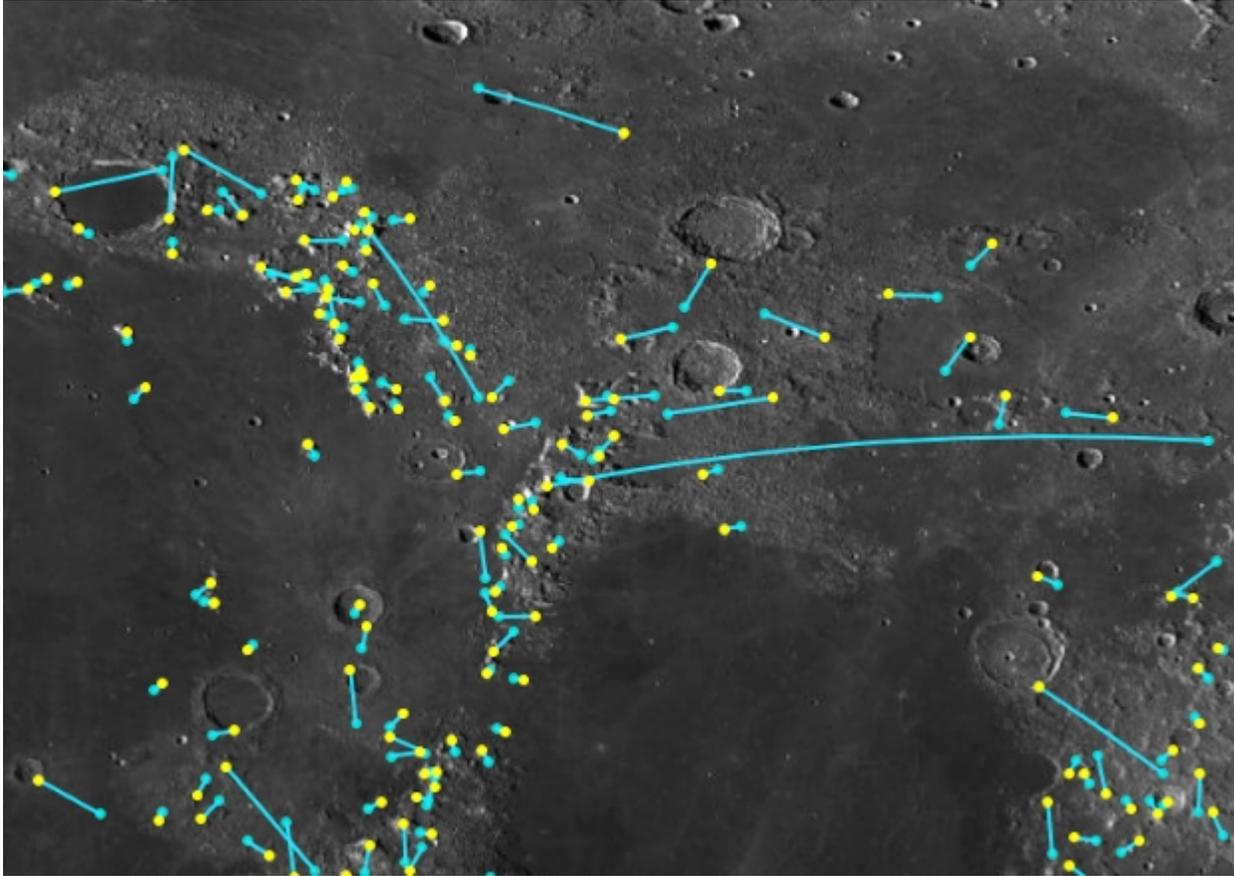

168

169 In the complex-crater example of Figure 2, the prominence (A-a) of the central peak  
 170 corresponds to its height above the crater floor, and prominence (B-b) corresponds to rim height  
 171 above the surrounding terrain. Unlike break-in-slope methods (e.g., Bray et al., 2008) or  
 172 DEM-histogram approaches (e.g., Kalynn et al., 2013) which require definitions of “floor,”  
 173 “rim,” or “pre-impact terrain,” prominence derives these relationships solely from the summit-  
 174 col pair. This makes it both complementary to those techniques and uniquely base-independent,  
 175 while also encoding the morphometric independence of each summit.

176 **Figure 2.** Plutarch crater. Labeled features are (A) Plutarch Beta, (B) Mons Plutarch. The  
 177 inset elevation profile across the crater shows these as a rim Ribu and a central-peak,  
 178 respectively.

179 Figure 3 depicts the distribution of Ribus in a nearside mare region, demonstrating that key  
 180 cols may occur over a wide range of positions and separations relative to their summits.

181

182 **Figure 3.** Regional view extending beyond the MONTES ALPES area of Figure 1, showing  
 183 a broader distribution of summits and their key cols. The longest connector visible  
 184 corresponds to the summit-key col pair of the most prominent summit within the Imbrium  
 185 Basin rings system: Mons Calippus C / Mons Elbruz.

## 186 **4. Lunar Ribus Database**

### 187 **4.1. Contents**

188 Each record contains:

- 189 • Unique ID number
- 190 • Summit name
- 191 • Summit latitude (°) and longitude (°)
- 192 • Summit elevation (m)
- 193 • Key col latitude (°) and longitude (°)

- 194 • Key col elevation (m)
- 195 • Topographic prominence (m)

## 196 **4.2. Availability**

197 The Lunar Ribus Database is provided as a comma-separated values (CSV) file containing  
198 one record per summit. It is archived on Zenodo and is accessible via DOI:  
199 <https://doi.org/10.5281/zenodo.19363869>. Users of the catalogue are requested to cite the  
200 catalogue DOI.

## 201 **4.3. Applications**

202 The Lunar Ribus Database enables:

- 203 • Hierarchical morphostructural classification
- 204 • Quantification of central uplifts in impact craters
- 205 • Basin-ring and massif segmentation
- 206 • Identification of mechanically independent crustal blocks
- 207 • Prominence-frequency distribution analysis
- 208 • Base-independent edifice height measurement
- 209 • Integration with IAU lunar nomenclature datasets

## 210 **5. Conclusion**

211 The Lunar Ribus Database provides a reproducible, globally consistent morphometric  
212 framework for kilometre-scale positive relief on the Moon. It establishes a structural basis for  
213 quantitative analysis of lunar topography and offers a foundation for comparative prominence  
214 studies across planetary bodies.
