Abstract:	The evolution of the rifted margin of the northern South China Sea challenges predictions of previous models but a knowledge gap still exists regarding how thermal history varies at different locations and times of rifting. International Ocean Discovery Program (IODP) Expeditions 367/368/368X collected samples of sediment that can be used to model the thermal evolution at different rifting stages in the distal margin and oceanic crust. Modelling results outline a thermal history driven by the interplay of different tectonic processes that are sometimes at odds with the main theoretical models. The most proximal location has a burial history that includes the unroofing of ~3km of sediment before the increase of heat flow during rifting and break up prior to cooling to the present day. In the more distal part, short, localised peaks in heat flow due to syn-rift magmatism are recorded while, the oceanic crust has a thermal regime decoupled from that of the continental section and here the rate of cooling abruptly decreased in final post-rift phases. Thus, while the transect drilled in IODP 367/368 may represent a transition from continental to ocean crust, the thermal regimens sampled by are not end-members in a simple continuum and instead capture fundamental steps in the thermal evolution of the distal rifted margin of the northern South China Sea. On a global scale, this dataset represents one of the most complete samplings of a distal rifted margin providing critical new constraints on the thermal evolution during formation of rifted margins.

New insights into rift evolution from data-constrained burial and thermal histories at the northern South China Sea margin

Abstract

The evolution of the rifted margin of the northern South China Sea challenges predictions of previous models but a knowledge gap still exists regarding how thermal history varies at different locations and times of rifting. International Ocean Discovery Program (IODP) Expeditions 367/368/368X collected samples of sediment that can be used to model the thermal evolution at

different rifting stages in the distal margin and oceanic crust. Modelling results outline a thermal history driven by the interplay of different tectonic processes that are sometimes at odds with the main theoretical models. The most proximal location has a burial history that includes the unroofing of ~3km of sediment before the increase of heat flow during rifting and break up prior to cooling to the present day. In the more distal part, short, localised peaks in heat flow due to syn-rift magmatism are recorded while, the oceanic crust has a thermal regime decoupled from that of the continental section and here the rate of cooling abruptly decreased in final post-rift phases. Thus, while the transect drilled in IODP 367/368 may represent a transition from continental to ocean crust, the thermal regimens sampled by are not end-members in a simple continuum and instead capture fundamental steps in the thermal evolution of the distal rifted margin of the northern South China Sea. On a global scale, this dataset represents one of the most complete samplings of a distal rifted margin providing critical new constraints on the thermal evolution during formation of rifted margins.

40

41 1. ***Introduction***

The thermal structure of rifted margins controls the rheological behaviour of continental lithosphere during continental break-up (Buck, 1991; Manatschal et al., 2006; Geoffroy et al., 2015; Pérez-Gussinyé et al., 2024) as well as the stratigraphic architecture and sedimentation (Pindell et al. 2014; Alves et al. 2020). Thermal evolution of sedimentary basins fostered an extensive scientific interest in the 1970s because of its implication in hydrocarbon generation (Sleep, 1971) that is, today, still critical for evaluating the potential to host resources for the energy transition (Pérez-Gussinyé et al., 2023).

The classical McKenzie model on stretched continental crust was developed in 1978 and considers an initial increase in heat flow (HF), culminating in a peak, followed by an exponential decline, with

51 both phases strongly controlled by the degree of stretching (i.e. β factor; McKenzie, 1978). By
52 contrast, the variation of oceanic crust depth and heat flow with age has been later constrained by
53 Stein and Stein (1992) by compiling globally collected present- day HF values.

54 However, the variation of thermal structure in space and over time for a rifted margin remains
55 largely unaddressed. There is most uncertainty about the evolution of distal rifted margins
56 characterized by extreme lithospheric thinning, polyphase tectonic and localized magmatic activity;
57 e.g. cases where variation is likely to be greatest. These domains remain poorly constrained mostly
58 due to the lack of extensive offshore drilling along present-day distal rifted margins. Where outcrops
59 exist the thermal history of initial sedimentary burial has been generally “overprinted” by
60 metamorphism during orogenic events that inverted the rifted margin and lifted it to the surface
61 (Beltrando et al., 2014). Only in specific cases, the thermal evolution of distal rifted margins
62 imbricated within orogenic systems is still preserved (Alps: Beltrando et al., 2015; Celini et al., 2023;
63 Pyrenees: Lescoutre et al., 2019; Saspiturry et al., 2020).

64 The only available studies of present-day distal rifted margins are based on 1) ODP and IODP
65 expeditions such as the Iberia-Newfoundland rifted margins (Callies et al., 2018) and the South China
66 Sea (Nirrengarten et al., 2020a) and/or 2) geophysical surveys such as the Iberia-Newfoundland
67 rifted margins (Welford et al., 2010), Red Sea (Girdler and Evans, 1977), Gulf of Aden (Lucazeau et
68 al., 2008), Guaymas Basin (Neumann et al., 2023), and the South China Sea (Zhu and Liu, 2025).

69

70 Studies and campaigns on present-day distal rifted margins suggest that geological features such as
71 polyphased rifting, sedimentation rate, localized magmatism or ridge jumps can affect the syn-rift
72 and post-rift thermal evolution (e.g. Neumann et al., 2023; Lucazeau et al., 2008). However, this has
73 never been verified by means of thermal maturity studies except for one location corresponding to
74 the Continental Ocean Transition (COT) of the South China Sea by Nirrengarten et al. (2020a).

75 Similarly, Lescoutre et al. (2019) and Saspiturry et al. (2020), in the fossil Iberian margin preserved
76 in the Pyrenean orogen, have compared the maximum temperatures reached at different rifting
77 stages calculated by numerical modelling with those qualitatively derived from reflectance and
78 Raman analyses on the organic matter. Noteworthy, in these works, a kinetics-based calibration
79 could not be applied because of very high thermal maturity, equating to or exceeding the onset of
80 metamorphism.

81

82 Amongst the cases available, the South China Sea (SCS) has a unique dataset combining IODP
83 Expeditions 367-368 -368X that sampled different crustal domains from the continental crust to the
84 oceanic domain with pre, syn and post rift sediments obtained (Larsen et al. 2018), geophysical
85 surveys and extensive seismic data (Gao et al., 2015; Lei et al. 2019; Ding et al., 2018; Deng et al.,
86 2020) enabling us to investigate the thermal evolution of a rifted margins in space from continental
87 crust to the oceanic crust and time across the rifting stages.

88 Results from these expeditions revealed a rapid lithospheric extension leading to sharp transition
89 between continental crust and oceanic crust with no mantle exhumation (Larsen et al., 2018; Mohn
90 et al., 2022; Zhang et al., 2024), along with localized magmatic activity during both rifting
91 (Nirrengarten et al., 2020a; Deng et al., 2020; Zhang et al., 2021) and post-rift phases (Lin et al.,
92 2019; Sun et al., 2019; Hung et al., 2021; Li et al., 2022; Sun et al., 2023) and a “rift-jump” at 27 Ma
93 and 23 Ma toward the present-day spreading centre (Barckhausen et al., 2014; Ding et al. 2018).

94 The present-day thermal state of the whole Northern margin of the SCS has also been studied by a
95 recent review (Zhu and Liu, 2025) outlining a general continent to the ocean HF increase with several
96 exceptions recognized due to changing tectonic settings and shallow environmental factors that
97 thus needs more investigation.

98 Here we present thermal histories for pre, syn- and post-rift sediments found at the distal rifted
99 margin (U1501), the COT (U1499, U1502) and the oceanic domain (U1500) of the South China Sea,
100 calibrated by organic proxies and relative kinetic models. Therefore, the full temperature time
101 evolution of the northern rifted margin of the SCS is assessed at different locations and successive
102 stages of rifted margin development, not only peak temperatures, presenting a unique dataset as a
103 valuable reference for comparison with other rifted margins across the world.

104

105 **2. Geological setting**

106 The South China Sea (SCS) is a marginal oceanic basin located in the western Pacific and surrounded
107 by continental units: the South China Block to the North, Indochina to the West and Palawan-Borneo
108 to the South-East and the Luzon Arc to the East (Fig. 1a). It can be divided into three main sub basins
109 (North West, East and South West, Fig. 1a) whose genesis relates to rift evolution. The tip of the V-
110 shaped oceanic basin points to the south-east indicating a propagation of seafloor spreading that
111 separated the northern China-Indochina margin from the Palawan-Borneo Block between ~33 Ma
112 and ~15 Ma (Taylor and Hayes, 1983; Briais et al., 1993). The rifting of the SCS initiated in a former
113 Mesozoic active continental margin that was generated by the subduction of the Paleo-Pacific plate
114 under SE Eurasia (Zhou et al., 2008) during the Jurassic and Early Cretaceous (Li et al., 2020).
115 Extension was suggest to have started in the late Cretaceous, based on evidence of development of
116 extensional basins and non-marine sediments in the Pearl River Mouth Basin (Fig. 1a; Ru and Pigott,
117 1986; Zhou et al., 1995). The main episode of rifting occurred in Northern rifted margin and its
118 conjugate margin located offshore Palawan, during late Eocene – early Oligocene that lead to
119 breakup and seafloor spreading of the NE sub-basin (Larsen et al., 2018). Different hypotheses have
120 been made on the cause of the rifting including: 1) roll-back of the subduction zone (Li et al., 2020);

121 2) slab-pull of a subducted proto South China Sea (Taylor and Hayes, 1983) or; 3) the collision
 122 between the Indian subcontinent and Asia (Tapponnier et al., 1990).

123
 124 Figure 1 a) Crustal thickness map of the South China Sea modified from Legeay et al. 2024). Location of the study area (in black) in
 125 the Northern margin. Acronyms: BB: Baiyun Basin; LB – Liwan Basin; NWSB – North West South Basin; ESB – East Sub Basin; SWSB –
 126 South West Sub Basin. b) Spot of the study area from Fig. 1a. In the rectangle the map of the top acoustic basement (Tg reflector;
 127 Larsen et al., 2018) has been superimposed on the bathymetric map by using similar colour (see legend for Tg depths). The location

128 of the four studied IODP sites is indicated by the white dots. Heat flow location and values from Zhu and Liu, 2025 are indicated with
129 the pale to dark brown dots. c) Seismic section with location of Site U1501, U1502, U1499 and U1500. The black line indicates the Tg
130 unconformity (see text below) while the dotted line the Moho's depth.

131

132 The analysis of thermal regime we present here is based on samples from four (U1499, U1500,
133 U1501 U1502) of the seven sites drilled by the IODP expeditions 367-368 and 368X (Fig. 1b) across
134 a ~90 km long section of the distal northern rifted margin (Fig. 1b and c) (Larsen et al., 2018): the
135 Outer Margin High (OHM), the COT and the oceanic crust that span over three margin-parallel
136 basement ridges, namely ridge A, B and C (Fig. 1b – sites C was not included in this work).

137 The OMH, sampled by site U1501, is a top basement high ~50 km wide composed of 15 to 20 km
138 thick continental crust that progressively thins oceanward (Fig. 1c; Sun et al., 2018) and separates
139 the Liwan sedimentary basin (LW, Fig. 1a) with a highly thinned continental crust to the north from
140 the distal rifted margin to the south (Fig. 1c). Ridge A is a faulted structural high which has a variable
141 top basement lithology: highly altered Mid-Ocean Ridge (MORB) basalts (U1502) and continental
142 pre- to syn- rift clastic sediments (U1499). It represents the Continent-Ocean transition as it has
143 characteristics of both continent and ocean basement (COT). By contrast, at Ridge B, a 7 km thick
144 landward-rotated fault block, the sampled basement recorded MORB basalts with pillow structures
145 (U1500, Fig. 1c) at the location of the C11n magnetic anomaly, interpreted as the first formed
146 oceanic crust (Larsen et al., 2018).

147

148 2.1 Stratigraphy

149 Using biostratigraphic and lithostratigraphic data from the four holes, combined with geodynamic
150 events of the SCS (Sun et al., 2018), the sedimentary sequences is divided into four main
151 depositional units (Fig. 2): late-post Rift (Neogene), early-post Rift (late Oligocene), syn-rift (Early
152 Oligocene to Eocene) and pre-rift (pre-late Eocene).

153 A more detailed stratigraphic information and lithologies are provided in Schito et al. (2026).

154

155 Figure 2 Stratigraphy and lithology of the four sites across the northern rifted margin of the SCS. Big-grey dots indicate location of
156 samples analysed for vitrinite reflectance; small-grey dots indicate samples analysed with GC-MS. Red dots indicate samples analysed
157 in Nirrengarten et al., (2020a)

158

159 2.1.1 Outer Margin High (OMH)

160 Site U1501 was investigated by four holes, our samples come from holes U1501C and U1501D
161 (Tables 1). The Neogene sequence is composed by 290 m thick clay-rich nannofossil ooze and
162 nannofossil ooze deposited in a deep-marine environment. The contact between the Neogene and
163 Oligocene sediments is characterized by a major unconformity (T60) dated at 24-28 Ma by Jian et
164 al. (2018), and Late Oligocene early post-rift and Early Oligocene to Eocene syn-rift successions are
165 more than 300 m thick and consist of variable amounts of clay, silt, and sand (Fig. 2). In the syn-rift

166 successions the oldest most reliable age control at the Eocene/Oligocene suggests the sandstones
167 are the base are Eocene in age. Below an unconformity at 598.91m, well-lithified sandstones with
168 unknown age represent the pre-rift succession.

169

170 2.1.2 Ridge A

171 At site U1499, the 929m thick Neogene Unit composed of clay, silt and sandstones and upper
172 Oligocene–upper Miocene reddish-brown claystone was sampled to characterize the post-rift
173 maturity, while undated gravels and breccias collected from the base of the boreholes represent
174 the syn-post rift stage (Fig. 2).

175 At site U1502 the few samples collected derive from the late-post-rift late Miocene clay interbedded
176 with silt and sands and from a thin layer of saddle dolomite that has been dated at the late Eocene
177 age suggesting deposition during a late syn-rift setting (Fig. 2).

178

179 2.1.3 Ridge B

180 Site U1500 the post-rift succession was samples from 400 to 1200m of depth and is composed by
181 late Miocene clay, silt and sands and by and early middle Miocene early-post-rift red clays (Fig. 2).
182 The base of the borehole is composed by 150m of unaltered Oligocene (MOR) basalts (Fig. 2).

183

184 **3 Methods**

185 3.1 Thermal maturity and modelling calibration

186 Organic proxies' kinetics are the most used in burial/thermal modelling at low diagenetic levels.
187 Vitrinite reflectance ($R_o\%$) and Hopane 22S and Sterane 20S were used to calibrate our models.
188 Sample's preparation and measurements for both organic petrography and biomarkers analyses are
189 described in Schito et al. (2026) including $R_o\%$ histograms.

190 Simplified reconstructions of burial and thermal histories of drilling sites from the SCS were
191 performed by using Basin Mod 2-D, a commercial software package for basin modelling. The main
192 assumptions made during modelling are that: (1) rock decompaction is constrained following
193 Sclater and Christie's method (1980), by fitting models to porosity data measured by the the
194 standard IODP procedure (Moisture and Density – MAD; Sun et al., 2018 and supplementary
195 material); (2) variations in seawater depth were modelled according to biostratigraphic data from
196 Jian et al. (2018), and surface temperatures (ST) and sediment water interface temperatures (SWIFT)
197 were taken from present-day measurements and corrected for paleo-latitudes; (3) thermal
198 modelling was performed using the Easy %Ro method based on Sweeney and Burnham (1990), while
199 hopane and sterane isomerisation was modelled according to the kinetic models proposed in
200 Mackenzie and McKenzie (1983); (4) heat flow during rifting was modelled according to McKenzie
201 et al., (1978).

202

203 **4 Results**

204 *4.1 Organic Thermal maturity*

205 Additional details regarding the dataset are provided in Schito et al. (2026).

206 *4.1.1 Outer Margin High – site U1501*

207 Assessing the level of thermal maturity of the post-rift to syn-rift Oligocene to Pliocene oozes from
208 site U1501 is difficult because of a low organic carbon content that makes organic petrography
209 impractical (TOC 0.40 -0.53 %), along with the shallow depth of burial (Tab. 1, Fig. 3 and Schito et
210 al., 2026) and overall low level of thermal maturity as described later. The presence of hopane
211 biomarkers with 17 β ,21 β (H) structure conformations is important as these biomarkers are only
212 stable at very low levels of diagenetic alteration (Farrimond et al, 1998). The values observed for a
213 thermal maturity parameter based on these 17 β ,21 β (H) hopanes for the Oligocene to Pliocene

sediments of U1501 is consistent with the shallow depth of burial even if it does not describe a downhole trend. Conversely, most samples from the U1501-Oligocene to Pliocene oozes values for the hopane 22S (0.35 to 0.65) and sterane 20S (0.3 to 0.6) thermal maturity parameters that are inconsistent with the depth of burial show the presence of 17 β ,21 β (H) Hopanes (Table 1) and sterane (Sup. Materials and Schito et al., 2026). The high values of hopane 22S and sterane 20S in most samples reflect an allochthonous input of reworked biomarkers. One sample at 308 meters depth (Tab. 1, Fig. 3b) likely reflects in-situ maturity for this interval with both collaborating hopane 22S and sterane 20S values of 0.14 and 0.17, and values that are reasonable for the sample's depth of burial and proportion of 17 β ,21 β (H) hopane. This provides the one calibration point that can be used for modelling the youngest section of U1501.

224

Table 1 Samples' names, relative depths and rift stages for site U1501 together with TOC, Ro% values with standard deviation and number of measurements and Hopane 22S, $\beta\beta$ Hopane and Sterane 20S parameters. Hopane thermal maturity parameters calculated from the m/z 191 ion chromatogram include: C_{31} hopane 22S = C_{31} 17 α ,21 β (H)-22S / [C_{31} 17 α ,21 β (H)-22S + C_{31} 17 α ,21 β (H)-22R]; C_{30} hopane $\beta\beta$ = C_{30} 17 β ,21 β (H) / [C_{30} 17 β ,21 β (H) + C_{30} 17 β ,21 α (H) + C_{30} 17 α ,21 β (H)]. Sterane thermal maturity parameters calculated from the m/z 217 ion chromatogram include: C_{29} sterane 20S = C_{29} 5 α ,14 α ,17 α (H)-20S / [C_{29} 5 α ,14 α ,17 α (H)-20S + C_{29} 5 α ,14 α ,17 α (H)-20R].

231

232

233 Vitrinite reflectance values range between 0.35 to 0.38 $R_o\%$ in the Eocene Syn-rift succession located
234 above the reflector Tg. The succession from U1501 has high TOCs from 1.31 to 5.14 % (except for
235 the deepest sample 0.11 %; Table 1). Under reflected light observation, the organic matter can be
236 seen to be mostly vitrinite, likely indicating a significant input of terrestrial sedimentary organic
237 matter. Biomarker data show some anomalous values in the Eocene of U1501 (Fig. 3 a and b), thus
238 the highest vitrinite value of 0.38 $R_o\%$ may be influenced by the allochthonous and reworked organic
239 matter.

240 Beneath the acoustic basement of U1501, in pre- late Eocene pre-rift succession, there is a jump in
241 thermal maturity with an observed vitrinite reflectance of 0.52 $R_o\%$ (Tab. 1, Fig. 3a) that is further
242 confirm by consistent increases in hopane and sterane thermal maturity parameters (Tab. 1, Fig.
243 3b).

Figure 3 a) thermal model calibration of vitrinite data and resulting maximum temperatures; b) thermal model calibration of hopane and sterane data; c) The figure shows the three scenarios used to fit post-rift data. Scenario 1: McKenzie's heat flow model for rifted margin using a beta factor of 2; Scenario 2: constant heat flow to present day values in the syn and post rift stages and 70 mW/m^2 in the pre-rift stage; Scenario 3: constant HF value of 70 mW/m^2 ; d) porosity data and calibrated curves. Sst in the stratigraphic legend stands for sandstones.

4.1.2 Ridge A – Sites U1499 and U1502

Results of the analyses of samples from ridge A were presented in Nirrengarten et al. (2020a) with the addition of a GC-MS analysis from site U1499 at 357m depth (Fig. 2 and Table S1 in sup. materials).

Figure 4 a) $R_o\%$ calibration and calculated maximum temperatures of U1499 well; b) Hopane 22S and Sterane 20S calibration model, of U1499 well; c) measured and calculated porosity evolution with depths, of U1499 well; d) The figure shows the three scenarios used to fit po-rift data. Scenario 1: heat flow evolution at the ocean-continent transition according to Mckenzie heat flow model for rifted margin using a beta factor of 4 and considering results from Nirrengarten et al., (2020a); Scenario 2; constant heat flow to present day values in the syn and post rift stages and 70 mW/m^2 in the pre-rift stage; Scenario 3: constant HF value of 70 mW/m^2 ; e) $R_o\%$ calibration and calculated maximum temperatures of U1502 well; f) hopane 22S and sterane 20S calibration model, of U1502 well; g) measured and calculated porosity evolution with depths, of U1502 well. RCI in the stratigraphic legend stands for red claystones, while Dol for dolomite.

265 Late-post rift shales and mudstones deposited during the early to middle Miocene at site U1502 and
 266 up to the late Pleistocene in U1499 have $R_o\%$ values between 0.26 and 0.57 (Tab. S1). TOC is also
 267 relatively high at 0.3 to 1.3 % reflecting good quality organic matter for petrographic analyses.
 268 Despite this, the two highest values of vitrinite reflectance (0.41 and 0.57 $R_o\%$) may reflect the
 269 presence of reworked material. This is validated by biomarker thermal maturity parameters that
 270 highlight a predominance of allochthonous material at the shallowest depths of site U1499 (Fig. 4),
 271 while the lowest values at the base of late-post Rift sediments confirm the low maturity detected
 272 by vitrinite reflectance (Fig. 4 b and Tab. S1 sup. materials).
 273 Biomarker hopane and sterane thermal maturity parameters (Table S1) also confirm low maturity
 274 in the early-post Rift sediments in both sites, where TOC values suggest insufficient organic matter
 275 for reliable $R_o\%$ measurements. Syn and pre-rift sediments, on the other hand, show an exponential
 276 increase of vitrinite reflectance values in borehole U1499 reaching a maximum value of 1.83 $R_o\%$ at
 277 the bottom of the well (Fig. 4a), while a vitrinite reflectance of 0.43 $R_o\%$ for the hydrothermally
 278 altered dolomite in U1502 is high for the depth of burial, but perhaps not excessively high
 279 considering the implied metasomatism (Tab. S1 and Fig. 4e).

280

281 4.1.3 Ridge B – Site U1500

282 TOC data from the Oligocene claystones at about 1300 m of depth show TOC values between 0.59
 283 and 0.66 and R_o value of 0.31 and 0.33% (Tab. 2), indicating an immature stage of hydrocarbon
 284 generation. Low maturities are further confirmed by Sterane and Hopane data in the Late Post Rift
 285 samples between 913 and 1185m of depth while the shallowest samples between 671 and 767m of
 286 depth indicate the presence of reworked material (Tab. 2 and Fig. 5).

287

295

296 4.2 Thermal modelling

297 Thermal histories were obtained for the OMH, Ridge A and Ridge B by evaluating which of three
298 basal HF-models (scenarios graphically illustrated in Figs. 3c,4d,5c) best recreates measurements of
299 vitrinite reflectance or the hopane 22s and sterane 20S thermal maturity parameters. These thermal
300 maturity parameters have kinetic models (models that explain the parameter as a function of both
301 heating duration and a given temperature) and thus may help in evaluating heat flow during past
302 stages of rift development. The match between measured and model-calculated petrophysical
303 parameters such as bulk density and thermal conductivity is also presented in tables and figures and
304 tables from S2 to S5 in the supplementary materials.

Figure 5 a) $R_o\%$ calibration and calculated maximum temperatures of U1500 well; b) Hopane 22s and Sterane 20s thermal maturity profiles; c) The figure shows the three scenarios used to fit po-rift data. Scenario 1: heat flow evolution at the ocean-continent transition according to McKenzie heat flow model for rifted margin using a beta factor of 4; Scenario 2: constant heat flow to present day values in the syn and post rift stages and 70 mW/m^2 in the pre-rift stage; Scenario 3: constant HF value of 70 mW/m^2 ; d) measured and calculated porosity versus depth. RCI in the stratigraphic legend stands for red claystones.

Scenario 1) presents the situation where HF is high during rifting but subsequently subsides according to the McKenzie et al., (1978) model and can be considered a model that reflects both crustal and deep earth processes in the form of its beta-factor; Scenario 2) has a heat flow that is low in the pre-rift (70 mW/m^2) that is an average value for an active continental margin for Allen and Allen (2013; see discussion below) and then elevated for syn- and post-rift stages up to the present day, and; Scenario 3) represents the simplest and most facile consideration of heat flow by assuming that it has not changed over time (70 mW/m^2).

321 Based on the present-day thickness of the crust (15km) at the OMH a beta factor of 2 was chosen
322 (Nirrengarten et al., 2020a,b). It was found that measurements of thermal maturity could be
323 recreated for syn- and post-rift successions by heat flow models constructed using Scenarios 1 and
324 2 (Fig. 3 a, b, c). A rise in heat flow is needed, but the low number of observations makes further
325 differentiation difficult. A model in which a maximum heat flow of 140 mW/m² is reached during
326 the climax of rifting at 30 My before cooling to the present-day value of 100 mW/m², was found to
327 still recreate thermal maturity, and this places a limit on the maximum heat flow subsequent to the
328 onset of rifting (Fig. 3c). For the acoustic basement (section beneath the Tg horizon) and the pre-
329 Eocene sediments, no rifting-based models of heat flow (Models after Scenario 1 that use beta
330 factors) could recreate the high thermal maturity indicated by both vitrinite reflectance and
331 biomarker data (i.e. there is jump in thermal maturity). Porosity is also much lower in the pre-Eocene
332 sediments, and in combination with thermal maturity and seismic observations (Larsen et al. 2018)
333 indicates the presence of an erosive unconformity. Adding 3 km of sedimentary burial and erosion
334 before the onset of rifting, created a basin model that reproduced measurements of both porosity
335 and thermal maturity. Thus, a lost burial history and particularly the erosion of overburden play an
336 important role in the thermal history at the OMH, while basal heat flows can be explained by a more
337 classical model of rifting (McKenzie, 1978).

338

339 For Ridge A (sites U1499 and U1502) previous work show a crustal thickness of 10 km suggesting an
340 extreme thinning associated with a beta factor of >3 (Nirrengarten et al. 2020a). In post-rift
341 sediments, heat flow models after Scenarios 1 and 2 (cooling subsequent to rifting or a steady at
342 110 mW/m²) were equally able to recreate thermal maturity measurements. However, for site
343 U1499 additional heat flow was needed for deeper units, and Nirrengarten et al., (2020a) invoked
344 the emplacement of a magmatic intrusion, at least 20 m thick, near to the site. The thermal aureole

345 around the intrusion must have started during the late syn-rift stage at the end of the Eocene and
346 lasted to the beginning of the Oligocene and did not affect post rift successions.

347

348 Ridge B, (site U1500), the most distal site with post-rift sediments deposited on ocean crust, has low
349 values of thermal maturity that cannot be predicted by heat flow models from Scenario 1 or 2, that
350 reflect the effects of heating subsequent to rifting of continental crust. Measurements of thermal
351 maturity at Ridge B were predicated by a constant heat flow of 70 mW/m² (Fig. 5).

352

353 **5. Discussion**

354 *5.1. A combined approach for shallow sedimentary successions*

355 Core samples from the IODP 367/368 offer the opportunity to model, for the first time, the evolution
356 of heat flow in a rifted margin across a continent-to-ocean transect.

357 In the relatively shallow successions of the SCS this is achieved by combining organic proxies
358 sensitive to early diagenetic transformation. The use of vitrinite reflectance is often limited by the
359 lack of vitrinite in non-clastic sediments or sediments at very low stages of thermal maturation (i.e.
360 pre-vitrinite), thus combining biomarker and vitrinite proxies was crucial to provide a continuous
361 thermal maturity profile along the OHM and Ridge A (Figs. 3 and 4), and to confirm thermal maturity
362 when only a few vitrinite reflectance measurements are made, such as beneath the Tg reflector in
363 U1501 or the sparse samples in U1500 and U1502. Furthermore, the presence of sterene and
364 17 β ,21 β (H) Hopanes (Schito et al., 2026), that are easily destroyed at high temperatures, suggest,
365 in shallow samples, that a high percentage of reworked material is present avoiding
366 misinterpretation during models' calibration (Wen et al., 2026).

Figure 6 a) Sterane 20S and b) $\beta\beta$ hopane data plotted against Hopane 22S (note here the inverse order of the y-axis). c) heat flow and d) burial histories used to model thermal maturity data. Sea-level variation has not been included in this graph but is has been used in modelling calibration. e) thermal maturity expressed as $R_o\%$ and Hopane 22S against the age of maturation used in modelling. $R_o\%$ in logarithmic scale. Note that reworked data has not been used in figure e.

However, determining thermal maturity from a single biomarker proxy is not advisable and consistency among different proxies should be checked (Aderoju and Bend, 2017). This can be shown in Fig. 6 a and b where Hopane 22S has been plotted against Sterane 20S (Fig. 6a) and $\beta\beta$ hopane (17 β ,21 β (H) Hopanes; Fig. 6b). Samples interpreted as exhibiting consistent changes in thermal maturity and thus can be taken as recording in-situ thermal alteration (big symbols). Reworked data (smaller symbols), mainly cluster in both upper right corners that correspond to the highest maturities.

Considering in-situ data alone, Figs. 6 a and b depict an increase in thermal maturity progressing from Pre-Rift to Late Post Rift samples. Late post-rift samples show the lowest level of thermal maturity and are associated with the shallowest depths at Ridge A and the OMH, and with depths beneath 1000m at Ridge B (U1500).

383 The calibration of models with vitrinite reflectance and biomarkers data allows increases in heat
384 flow across the OHM and Ridge A at 30 My (Fig. 6 c) during the main phases of burial to be
385 determined: one increase in just the OHM, at the end of Mesozoic before rifting of the SCS (dotted
386 line in Fig. 6 d) and another, related to the increase in sedimentation rate from the last 10 My up to
387 the present day in ridges A and B (solid and dash dotted lines in Fig. 6 d). Such phases, give us the
388 timing of maturation of our samples as shown in Fig. 6 e, where for simplicity all thermal maturity
389 data have been converted into $R_o\%$ equivalent according to models' results. The causes of
390 differences in the timing of maturation across the rifted margin reflects geodynamic events specific
391 to each site that have occurred since the end of Mesozoic and are discussed below.

392

393 *5.2. Thermal evolution of the northern rifted margin of the SCS*

394 *5.2.1. OMH – A Mesozoic history recorded by pre-rift successions*

395 Models of thermal evolution at the OMH (Fig. 3c) require that from 30 Ma HF decreased from a peak
396 at the time of breakup, or that HF was maintained constant at a similar value to the present day.
397 Prior to the Eocene and mostly likely prior to Cenozoic rifting, based on thermal maturity and
398 porosity considerations, the OMH was buried under a 3km thickness of sediment and thus has a lost
399 portion of its burial history. That needs further consideration.

400 Pre-rift successions comprise well-lithified and poorly sorted arkose with a high plagioclase content
401 ranging from 30 to > 60 % that were likely derived from diorite or granodiorite or basement of
402 intermediate composition. The age of the unit is not constrained because of the lack of fossils.
403 However, across the Pearl River Mouth Basin (Fig. 1), the Tg horizon that marks acoustic basement
404 is usually a boundary between Eocene and Mesozoic sediments, representing a hiatus thought to
405 have lasted from Late Cretaceous to Paleogene (Yan et al., 2014). During the late Mesozoic, in the
406 OMH, was an active continental margin, forming above a Paleo-Pacific subduction zone (Fig. 7a; Li

et al., 2019; Xu et al., 2016). Sediments deposited at this time derived from the products of a Mesozoic Andean-type volcanic arc located to the front of present day coastal Southern China (Fan et al., 2022) and the Pre-rift sandstone, have a mineral composition that is near to intermediate (low in ultramafics and relatively low in quartz) largely consistent with this tectonic setting.

Both porosity and multiple thermal maturity parameters place strong limits for minimum burial for the sediments beneath Tg at U1501 (Fig. 3d). It is important to note that a burial of not less than 3 km is indicated, and a deeper burial might be possible if sediments accumulated in a basin with a low heat flow (Fig. 3 a,b,d). Within 1D basin modelling both tectonic burial (burial due to overthrusting) and burial beneath sediments need to be considered. Considering a tectonic burial is it known that regionally a late Mesozoic compression led to the development of nappe stack (Ye et al., 2018) but only a gentle folding has been observed in some seismic sections in the basement of the OMH (Larsen et al. 2018). As well, folds and thrust faults below the Tg in the Baiyun-Liwan Sag exists (Zhao et al., 2020). Therefore, a tectonic loading due to thrusting and equivalent to >3 km of burial is still possible but difficult to demonstrate within currently known tectonic frameworks for the site. Conversely, burial beneath a thickness of 3 km of sediment in a forearc setting (Fig. 7a), as demonstrated for similar settings, is a more conservative explanation (Gusmeo et al., 2022).

Regardless of the type of burial the pre-rift thermal history of the OMH requires the removal of 3 km of sediment.

The first event that may be responsible for removal of sediment prior to the Eocene is the development of the Eurasian active continental margin and its associated uplift and erosion of sediments (Fig. 7b; Shi and Li, 2012). This would have occurred prior to the onset of rifting during the Mesozoic and early Cenozoic in the SCS. The second event is associated with the formation of the adjacent Liwan basin (a sub-basin of the PRMB) to the north, that lead to rift flank uplift of the OMH during Cenozoic rifting (Lei et al. 2019). Lei et al (2019) suggested an age for this uplift of Late

431 Eocene-early Oligocene based on the absence of the the Enping Formation (32-38 My) in a nearby
432 well drilled in the Liwan basin. However, the poor dating of the oldest pre-rift sandstones in
433 borehole U1501, does not exclude an earlier age for the uplift or unroofing in part or whole and
434 given the amount of sediments removed it is more probable most of the erosion was linked to the
435 pre-Eocene regional uplift (Fig. 7b).

436

437 *5.2.2. Ridge A – Syn-rift magmatic emplacement at the COT*

438 Thermal evolution of Ridge A is already detailed in Nirrengarten et al. (2020a), who interpreted the
439 high thermal maturities of syn- to pre-rift sediments to be a consequence of localised aureoles
440 generated by magma emplacement during the continental break-up. Late and early post rift
441 sediments have thermal maturities that can be explained by a paleo HF just above or equal to that
442 of the present day (Fig. 4). Thus, in difference to the OMH, thermal evolution at the Ridge A is
443 dominated by magmatism associated with break-up that produced locally heating and cooling at a
444 shorter timescale than that of the entire crust (Fig. 7c).

445 Similarly to the OMH, the magmatism (at least at shallow levels) stopped after rifting and the
446 thermal evolution at Ridge A during the burial of post-rift sediments corresponded to a cooling from
447 peak heat flows (Scenario 1) or continuation of present-day values (Scenario 2; Fig. 4).

448

449 *5.2.3. Ridge B – Thermal evolution on the oceanic crust*

450 Thermal Evolution at Ridge B does not correspond to a McKenzie (1978) styled model of rifting of
451 continental crust, nor to the Stein and Stein (1992) model for oceanic domain, nor can it be
452 explained by a steady state model. However, complicating the assessment of thermal evolution at

Figure 7 Tectonic evolution of the Northern rifted margin of the SCS according to outcomes from thermal models showing a) the Late Cretaceous active margin stage, b) condition at the onset of the Cenozoic rifting, c), d) development of the Cenozoic rifting and continental breakup, e) present-day stage.

457 U1500, Ridge B, is the use of a HF extrapolated from older sites (Nissen et al., 1995) or by comparison
458 with the nearby U1499 site (Sun et al., 2018), as well as the generally low thermal maturity of the
459 late post-rift succession.

460 According to our data, a HF value of at least 70 mW/m² since the early Oligocene (Fig. 5) could
461 recreate thermal maturity in the post rift sediments even if, considering the age of the oceanic crust
462 (30 Myrs old) and the proximity to Sites U1499 and U1502 a higher HF close to 100mW/m² should
463 be expected.

464

465 However, oceanic spreading in this region is interpreted to have been associated with migration of
466 the spreading centre during the formation of first igneous crust (Nirrengarten et al., 2020b)
467 Asymmetric migration of spreading centre may have triggered slow-moving asthenospheric mantle
468 material southward of ridge B during the establishment of stable seafloor spreading, leading to
469 cooler conditions. In addition, the Ridge jump during 27Ma to 23 Ma (Barckhausen et al., 2014; Ding
470 et al., 2018) may have further cooled the ridge B (Fig. 7 d and e). The causes of the Ridge jump are
471 still not fully understood, but it has been proposed to be related to a far-field stress effect, induced
472 by the adjacent Palawan-Borneo orogenesis linked to the subduction and closure of the Proto-South
473 China Sea (Chang et al., 2022). As result, the thermal evolution of Ridge B and present-day low HF
474 are related to the dynamics of seafloor spreading and it could be also speculated that the rapid
475 cooling of the crust enhanced the thermal subsidence at Ridge B.

476

477 *5.3. The distal rifted margin of the Northern SCS in a global framework of rifted margins*

478 The thermal evolution of the distal rifted margin of the northern SCS described above differs in some
479 ways from models previously proposed, but shares similarities with similar settings worldwide.

480 By using proxies of thermal maturity for which kinetics models are available it was possible for the
481 first time to determine HF at different stages of rifting at different locations along the continent to
482 ocean transect. Previous works determined thermal evolution at an extremely thinned continental
483 crust mainly based on numerical modelling of HF values that were at most validated only by
484 qualitative comparisons to vitrinite reflectance and Raman data (Lescoutre et al., 2019; Saspiturry
485 et al., 2020). Direct measurements of heat flow are only available for basins where spreading is still
486 ongoing at the present-day at basins like the Gulf of Aden and the Guaymas basin, or where recently
487 active as in the SCS (Lucazeu et al., 2008; Neumann et al., 2019; Zhu and Liu, 2025).

488 Comparison with other approaches are not so straightforward since is not easy to find cross sections
489 similar to ours, but despite this some synergy is observed. A good comparator can be made to
490 Lescoutre et al. (2019) that document the transition along the Pyrenean rift, while Pérez-Gussinyé
491 et al. (2024) model a full margin from continent to spreading ridge by varying sedimentation rates.
492 Balázs et al. (2023) also model the Côte d'Ivoire margin, providing a reference for proximal settings.

493 Present-day post-rift heat-flow data for rifted margins and continent–ocean transitions (COT) come
494 from Lucazeu et al. (2008) in the Gulf of Aden, with complementary oceanic-crust values from
495 Lucazeu et al. (2008) and Neumann et al. (2023) in the Guaymas Basin. Zhu and Liu (2025) provide
496 additional heat-flow observations from the northern South China Sea, showing similarly high heat
497 flow at the COT and lower values toward the oceanic crust.

498 These data are summarized in Fig. 8 where the red line indicates our calculated HF histories, the
499 orange polygons indicate the ranges of HF values at each stage from the abovementioned works
500 and the shaded green and red rectangles the present-day data from the Gulf of Aden, Guaymas
501 basin and SCS.

502 As a first assumption to interpret the figure, it is worth nothing that we consider only the shape of
503 the HF histories independently of the duration of the rifting. In practice it means the skewness of

504 the curve is normalized based on a common duration, which is divided into the three main stage of
 505 rifting (Fig. 4).

506

507

508 Figure 8 Comparison between the SCS thermal history calculated in this work and those from other studied margins and present-day
 509 data.

510 At the proximal margin, the pre-rift evolution is driven by relatively shallow subsidence probably in
 511 a forearc setting, with sediment derived by the erosion of a magmatic arc. This active margin setting
 512 is directly followed by a late Mesozoic and early Cenozoic post-orogenic extensional event and the
 513 Cenozoic rifting likely without thermal equilibration in-between.

514 This is substantially different from other rifted margins like the North Atlantic, the Tethys or the
 515 Red-Sea/Gulf of Aden where a thickened crust after continental collision (i.e. Variscan or Pan-African
 516 orogens respectively) was present and reequilibrated before the start of the subsequent rifting.

517 In the SCS, the lithosphere was probably in high thermal conditions and weakened by the large
 518 amount of water released by the subduction of the Pacific (Nirrengarten et al. 2020b; Wang et al.,
 519 2019).

520 As shown in Fig. 8 the SCS evolution follows the general trend calculated in previous works, even if
521 towards the highest values. Here the maximum values do not exceed the 140 mW/m^2 (more or less
522 the peak calculated in our models). It has to be considered that no real constraint exists on these
523 values since the heat generated was not enough to overcome the heating produced by the Mesozoic
524 burial. However, this is a maximum estimation, since higher values would have overcome the
525 temperatures of about $80\text{-}100^\circ \text{C}$ reached during pre-rift burial.

526

527 In contrast, the thermal evolution of the distal margin, including the hyper-thinned continental crust
528 and the COT appears much more variable. In the early Cretaceous fossil Pyrenean rift, characterized
529 by hyper-thinned continental crust, the maximum heat flow (HF) can reach up to 300 mW/m^2 then
530 decreasing to approximatively 100 to 70 mW/m^2 at present day, as calculated by Lescoutre et al.
531 (2019).

532 At the COT, the highest values reached in other basins are $\sim 200 \text{ mW/m}^2$ at the breakup time
533 according to the models by Perez-Gussinye et al. (2024) and the classical rift model (McKenzie,
534 1978). However, as shown in Nirrengarten et al. (2020a) in the SCS at the COT, HF increases can be
535 locally higher at the time of breakup than predicated by models.

536 Locally these higher temperatures are present and driven by syn-rift magmatism in a similar way to
537 the present-day in the Guaymas basin, where sills intrusions and associated hydrothermalism
538 produce short-lived elevated anomalous HF, and then subsequent cooling which is more rapid than
539 typical cooling of crust (Neumann et al., 2023). HF value can be kept up to the present-day as
540 observed in the Gulf of Aden (green rectangle in Fig. 8) related to recent post-rift volcanism
541 (Lucazeau et al. 2008).

542 The high HF at both OHM and Ridge A is likely related to the presence of deep-seated magmatic
543 bodies recognized at the base of the crust in the Pearl River Mouth Basin, that have been linked by

544 many authors (Lin et al., 2019; Sun et al., 2019; Hung et al., 2021; Li et al., 2022; Sun et al., 2023) to
545 the post-rift magmatism in the area (Fig. 7 d).

546

547 In the ocean domain, the Gulf of Aden follows the Stein and Stein (1992) or Goutorbe (2010) models
548 after the syn-rift peak (Lucazeu et al., 2008). The SCS however clearly deviates from this expected
549 behaviour at Ridge B. Here, possibly because of lithosphere heterogeneities, crustal deformation
550 has moved through time producing the so-called “Ridge Jumps” that stop both deformation and
551 excess heating. Ridge-jumps are also known in the Woodlark basin in the Pacific (Goodliffe and
552 Taylor, 2007) where, on the other hand, the effect on cooling has still not been verified. What we
553 demonstrated for Ridge B at the northern margin of the SCS is a slowing in rate of maturation,
554 following the ridge-jump at 23 My, ultimately producing values that are lower and comparable with
555 those used to model the SCS.

556 What can be picked up from Fig. 8 is that, in literature a general increase of the HF is always depicted
557 moving from the proximal to the distal margin related to continental lithosphere thinning. The
558 northern rifted margin of the SCS doesn't fit this pattern showing the highest localized HF at the
559 COT during syn-rift stages, conserving positive thermal anomalies at the proximal margin and COT
560 (probably due to deep-post and shallow-syn-rift magmatism respectively) and then a drop from the
561 last 10 Ma in oceanic crust in response to ridge-jump.

562

563 **6. Conclusion**

564 This study investigates the distal rifted margin of the northern SCS using an integrated approach
565 based on organic petrography and biomarkers, allowing us to unravel the thermal evolution of the
566 sedimentary successions deposited during the pre-, syn- and post-rift stages.

567 Using the results of the IODP expeditions 367/368, we studied the thermal maturities at four sites
568 across different structural domains (OMH; ridges A and B). These results were used to calibrate four
569 thermal models.

570 The thermal evolution of the distal rifted margin of the SCS is characterized by a heterogeneous
571 distribution of thermal maturity in pre-, syn-, and post-rift sediments, spanning from the continental
572 to the oceanic domains. These variations in thermal maturity are linked to different tectonic events
573 that shaped the formation of the SCS.

574 At Site U1501 (OMH), the preceding Mesozoic Yanshanian orogeny contributed to localized burial
575 of pre-rift sediments, influencing their thermal maturity. During the syn-rift stage, extreme thinning
576 of the continental lithosphere and high HF were dominant factors. Instead, thermal maturity in
577 these sediments was likely influenced by localized events, such as magmatic intrusions and
578 extrusions associated with rifting and continental breakup that had localized effects over shorter
579 timescales.

580 The post-rift phase is generally characterized by a low thermal maturity trend, with localized
581 anomalies and contrasts between the continental and oceanic sections. On the continental side,
582 significant post-rift magmatic activity may have caused localized thermal anomalies in the
583 sediments. In the oceanic domain, the instability of seafloor spreading resulted in complex mantle
584 dynamics, driven by seafloor spreading migration and ridge-jumps.

585 These new results from the distal rifted margin of the northern SCS represent a unique dataset for
586 global comparison with other rifted margins worldwide and provide key constraints on their thermal
587 evolution.
