## ABSTRACT

13 Over 90% of the build up of additional heat in the earth system over recent decades is contained  
14 in the ocean. Since 2006 new observational programs have revealed heterogeneous patterns of  
15 ocean heat content change. It is unclear how much of this heterogeneity is due to heat being added  
16 to and mixed within the ocean leading to material changes in water mass properties or due to  
17 changes in circulation which redistribute existing water masses. Here we present a novel diagnosis  
18 of the ‘material’ and ‘redistributed’ contributions to regional heat content change between 2006  
19 and 2017 based on water mass theory. We show that material warming has large spatial coherence.  
20 The material change tends to be smaller than the redistributed change at any geographical location,  
21 however it sums globally to the net warming of the ocean, while the redistributed component sums,  
22 by design, to zero. Material warming is robust over the time period of this analysis, whereas the  
23 redistributed signal only emerges from the variability in a few regions. In the North Atlantic, water  
24 mass changes indicate substantial material warming while redistribution cools the subpolar region  
25 due to a slowdown in the Meridional Overturning Circulation. Warming in the Southern Ocean is  
26 explained by material warming and by anomalous southward heat transport of  $118 \pm 50$  PW due to  
27 redistribution. Our results suggest near term projections of ocean heat content change and therefore  
28 sea level change will hinge on understanding and predicting changes in ocean redistribution.

## 29 **1. Introduction**

30 Over the past 50 years, as atmospheric greenhouse gas concentrations have increased, the ocean  
31 has absorbed more than ten times as much heat as all other components of the climate system  
32 combined (Rhein et al. 2013). This warming showed substantial spatial variability between 1993  
33 and 2005, being up to ten times greater in some regions than the global average (Zhang and  
34 Church 2012). It is unclear whether this variability is due to geographical variation in the interior  
35 propagation of surface warming versus redistribution of existing heat within the ocean.

36 Ocean warming is an important issue because ocean thermal expansion is the largest projected  
37 contribution to global mean sea level rise in the 21st century (Church et al. 2013). Numerical  
38 climate models disagree on the pattern and amplitude of ocean heat content (OHC) change and  
39 hence sea level rise under anthropogenic greenhouse warming (Gregory et al. 2016). Understanding  
40 how heat has been taken up and redistributed by the ocean is essential for predicting future changes.

41 Mesoscale eddies and planetary wave processes drive variability in ocean temperature at 10-  
42 100km spatial scales and typically dominate differences between ship based observations spaced  
43 years apart. Most striking of these is the El Niño Southern Oscillation which lifts the thermocline  
44 in the western Pacific and lowers it in the east leading to an exchange of heat between shallow and  
45 deep layers. This oscillation dominates observed global mean temperature variability (Roemmich  
46 and Gilson 2011).

47 Numerical ocean models forced with historical atmospheric conditions have proved to be useful  
48 tools in quantifying the role of atmospheric forcing in setting regional variability in OHC (Drijfhout  
49 et al. 2014) and sea level (Penduff et al. 2011). However such models can be ineffective in simulating  
50 underlying climate change due to model drift and inaccuracies in model forcing, particularly global  
51 mean heat fluxes (Griffies et al. 2009). On the other hand coupled ocean atmosphere climate

52 models are routinely used to capture the effect of climate forcing. But such models only accurately  
53 simulate past unforced variability in regional OHC when, by chance, their internal variability is in  
54 phase with the observed system.

55 An advancement in terms of numerical ocean climate modeling has been the separation of OHC  
56 change into an ‘added’ and a ‘redistributed’ component in climate model simulations, where the  
57 former is due to change in the surface heat flux, and the latter due to rearrangement of existing  
58 OHC because of altered ocean heat transports (Banks and Gregory 2006). This decomposition  
59 is analogous to the ‘anthropogenic’ and ‘natural’ decomposition, that has revolutionized our  
60 understanding of oceanic carbon records (Khatiwala et al. 2013). Here we will present a novel  
61 method to diagnose the ‘material’ component of OHC change which we will show is closely related  
62 the ‘added’ component introduced by Banks and Gregory (2006).

63 Recent work has aimed to reconstruct the drivers of OHC change based on observationally  
64 derived air-sea boundary conditions. Zanna et al. (2019) for example used surface temperature  
65 anomalies combined with a tracer based approach to reconstruct the role of anomalous surface heat  
66 fluxes in centennial heat content change. Roberts et al. (2017) estimated the contribution of air-sea  
67 heat flux changes in setting mixed layer and depth integrated OHC budget over recent decades  
68 and inferred the role of ocean circulation as a residual. Here we aim to circumvent reliance on  
69 such boundary conditions and infer the mechanisms of ocean heat content change directly based  
70 on water mass changes.

71 Water mass based methods have been used to decompose local temperature and salinity changes  
72 into a dynamic ‘heave’ components and apparently material effects at constant density based on a  
73 one dimensional view of the water column (Bindoff and McDougall 1994). However broader scale  
74 horizontal motions influence ocean temperature on longer timescales and indeed vertical heaving  
75 does not directly affect regional depth integrated OHC.

76 In the present work we present a new method based on water mass theory with which we estimate  
77 recent drivers of three dimensional OHC change. In Section 2 we will review water mass theory  
78 and establish the relationship between changes in water masses as defined by their temperature and  
79 salinity and material changes in sea water temperature. We will describe in Section 3 how this  
80 theory is translated into a practical method to estimate material changes in water masses and map  
81 these into geographical space. We present results of an application of this method to recent data  
82 over the Argo period in Section 4. We discuss the results and compare them with existing work in  
83 Section 5 and give conclusions in Section 6.

## 84 **2. Theory**

85 Water mass analysis has long been used in physical oceanography to trace the origin of waters  
86 (Montgomery 1958). In the latter half of the 20th century a quantitative framework emerged to  
87 describe the relationship between water masses, air sea fluxes and mixing (Walín 1982). (See  
88 the review by Groeskamp et al. (2019).) Recent work has seen this framework advanced in  
89 two ways specifically relevant to our work here: to multiple tracer dimensions to understand the  
90 thermodynamics of ocean circulation (Nycander et al. 2007; Zika et al. 2012; Döös et al. 2012;  
91 Groeskamp et al. 2014; Hieronymus et al. 2014) and to unsteady problems to understand the ocean's  
92 role in transient climate change (Palmer and Haines 2009; Evans et al. 2014; Zika et al. 2015a,b;  
93 Evans et al. 2017, 2018).

94 An example of the utility of the water mass transformation framework in understanding transient  
95 change is provided by Zika et al. (2015a). The distribution of water in salinity coordinates is  
96 influenced by the water cycle and turbulent mixing, the latter only being able to collapse the range  
97 of salinities the ocean covers. This means that changes in the width of the salinity distribution  
98 indicate an enhancement of the water cycle and/or a reduction in that rate at which salt is mixed. In

99 this project we extend this concept to consider how changes in the temperature-salinity distribution  
 100 relate to material changes in water masses.

101 Material changes in conservative temperature (here after  $T$ ) following the motion of an incom-  
 102 pressible fluid are related to Eulerian changes and advection by

$$\frac{DT}{Dt} = \frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T \quad (1)$$

103 where  $\mathbf{u}$  is the 3D velocity vector and  $\frac{DT}{Dt}$  is the material derivative which is related to sources  
 104 and sinks of heat and irreversible mixing.

105 Even if a perfect record of perfect record of  $\frac{\partial T}{\partial t}$  were available at a fixed location, (1) does not  
 106 give information regarding the relative roles of advection ( $\mathbf{u} \cdot \nabla T$ ) and material processes ( $\frac{DT}{Dt}$ ). We  
 107 therefore consider the water mass perspective as an alternative to the Eulerian perspective. The  
 108 following theory draws directly from Hieronymus et al. (2014).

109 We characterize water masses by their  $T$  and absolute salinity (here after  $S$ ). The volume of  
 110 water per unit  $T$  and  $S$  at  $T = T^*$  and  $S = S^*$  is

$$v(T^*, S^*) = \frac{\partial^2}{\partial T \partial S} \int_{T < T^*, S < S^*} dV. \quad (2)$$

111 Considering all the water in the climate system and retaining the incompressibility assumption,  
 112 the only way  $v$  can change is via ‘transformation’. That is, by making water parcels warmer, colder,  
 113 saltier or fresher. This realization permits the following continuity equation

$$\frac{\partial v}{\partial t} + \frac{\partial}{\partial T} (v\dot{T}) + \frac{\partial}{\partial S} (v\dot{S}) = 0. \quad (3)$$

114 Here  $\dot{T}$  is the average material derivative of  $T$  within a water mass. That is

$$\dot{T}(T^*, S^*) = \frac{1}{v} \frac{\partial^2}{\partial T \partial S} \int_{T < T^*, S < S^*} \frac{DT}{Dt} dV \quad (4)$$

115 and likewise  $\dot{S}$  is the average material derivative of  $S$ .

116 In (3) the terms  $v\dot{T}$  and  $v\dot{S}$  are the transformation rates in the temperature and salinity directions  
117 respectively. Equation (3) states that the amount of water between two closely spaced isotherms  
118 ( $T$  and  $T + \partial T$ ) and isohalines ( $S$  and  $S + \partial S$ ) will go up, if more water is made warmer at  $T$  than at  
119  $T + \partial T$  and/or more water is made saltier at  $S$  than at  $S + \partial S$  (i.e. more water comes in than goes  
120 out).

121 Here we will use changes in  $v$  to infer  $\dot{T}$ . This will allow us to estimate the material processes  
122 influencing ocean temperature change.

123 Note that although  $\frac{DT}{Dt}$  is controlled purely by heat sources and sinks and mixing and not ocean  
124 circulation. Therefore advection has no role in water-mass ( $T-S$ ) space, presuming it does no  
125 mixing, but this does not imply that it has no role in geographical space. Consider for example  
126 material warming which is detected within a deep water mass disconnected from the air-sea  
127 interface. Heat must have been mixed into that water mass but the heat may have been ‘added’  
128 to the sea surface, advected to the deep water mass and then mixed into that water mass. In the  
129 Appendix we will indeed show that our water mass based material temperature change corresponds  
130 closely with simulated ‘added temperature’ in an ocean model where explicit anomalous heat fluxes  
131 are prescribed and the corresponding temperature anomaly is tracked as a tracer throughout the  
132 ocean.

### 133 3. Method

134 Observational estimates of  $T$  and  $S$  come from the Enact Ensemble (V4.0, here after EN4, Good  
135 et al. 2013) for each month between 2006 and 2017 inclusive. We split these data into two periods  
136 of time: an ‘early’ period between 2006 and 2011 inclusive and a ‘late’ between 2012 and 2017  
137 inclusive. We then define a discrete set of water masses for each time period by splitting the ocean

138 into nine geographical regions and within each region by splitting the ocean up according to  $T$ - $S$   
139 bins.

140 Our nine geographical regions are defined: the Southern Ocean south of  $35^{\circ}\text{S}$ , the subtropical  
141 Pacific and Atlantic Oceans between  $35^{\circ}\text{S}$  and  $10^{\circ}\text{S}$ , the Indian Ocean north of  $35^{\circ}\text{S}$ , the tropical  
142 Pacific and Atlantic Oceans between  $10^{\circ}\text{S}$  and  $10^{\circ}\text{N}$ , the North Pacific north of  $10^{\circ}\text{N}$ , the Atlantic  
143 Ocean between  $10^{\circ}\text{N}$  and  $40^{\circ}\text{N}$  and the Atlantic and Arctic Ocean north of  $40^{\circ}\text{N}$ . To avoid  
144 discontinuities in our resulting analysis we transition linearly from one region to another over a  $10^{\circ}$   
145 band (Figure 2).

146 We define  $T$  and  $S$  bin boundaries ( $[T_{min}, T_{max}]$  and  $[S_{min}, S_{max}]$  respectively) using a quadtree  
147 method. The quadtree method starts with a single (obviously oversized) bin with  $T$  boundaries  
148  $[-6.4^{\circ}\text{C}, 96^{\circ}\text{C}]$  and  $S$  boundaries  $[-5.2\text{g/kg}, 46\text{g/kg}]$  in which the entirety of the ocean's sea  
149 water resides. The single bin is then split into 4 equally sized bins with the same aspect ratio as  
150 the original bin. The same process of splitting into four is repeated for any bin whose volume  
151 change is greater than a threshold of  $62 \times 10^{12}\text{m}^3$  (equivalent to the volume of a  $5^{\circ}$  longitude by  
152  $5^{\circ}$  latitude region at the equator with a depth of 200m) or until the bin size is  $0.4^{\circ}\text{C}$  by  $0.2\text{g/kg}$ .  
153 In the supplementary text we show that changing the size of these bins by a factor of two does not  
154 substantially change our results.

155 The quadtree method is applied within each region and for the change between the late and early  
156 periods. This results in bin edges defining 1447 water masses. These bins are then used to define  
157 both the 'early water masses' and the 'late water masses'.

158 The  $i$ th early water mass is described by its geographical region (from one to nine), its volume  
159 ( $V1_i$ ), its volume weighted mean temperature ( $T1_i$ ) and its volume weighted mean salinity ( $S1_i$ ,  
160 Fig. 2). Likewise, the  $j$ th late water mass is described by its region, volume ( $V2_j$ ), temperature  
161 ( $T2_j$ ) and salinity ( $S2_j$ ).

162 To change the water mass distribution from that of the early period to that of the late period  
163 requires that water be ‘transformed’ in  $T$ – $S$  space. When water transforms it changes its  $T$  and  $S$   
164 either in the same geographical region or as it moves to a region nearby. Transformation between  
165 early and late water masses is described by a matrix  $g$ . The  $i$ th column and  $j$ th row ( $g_{ij}$ ) corresponds  
166 to the average transformation of water from early water mass  $i$  to late water mass  $j$  in units of  $\text{m}^3$   
167  $\text{s}^{-1}$  over some time period  $\Delta t$ . Note that even if the  $i$ th water mass for the early period has the  
168 same temperature and salinity bounds as the  $i$ th water mass of the late period, the distribution of  
169 properties within the bin can change, so the average temperature and salinity of the water within  
170 the bin can change. That is, in general  $T1_i \neq T2_i$  and  $S2_i \neq S1_i$ , so  $g_{ij}$  is always a ‘transformation’,  
171 even with  $i = j$ .

172 Since the total volume of water is conserved from the early to late periods the following volume  
173 budget is applied

$$V1_i = \Delta t \sum_{j=1}^N g_{ij} \quad \text{and} \quad V2_j = \Delta t \sum_{i=1}^N g_{ij}. \quad (5)$$

174 Our goal is to estimate the matrix  $g$ . Out of the infinite number of choices which could satisfy  
175 (5), we find a ‘minimum transformation’, using an Earth Mover Distance (EMD) algorithm (Pele  
176 and Werman 2008, 2009). The EMD solves the hypothetical problem of moving earth from a set  
177 of mounds, each with varying amounts of earth, into a set of holes with varying amounts of empty  
178 space to be filled. The optimization problem is to find the smallest total mass weighted distance  
179 that needs to be travelled in order to empty the mounds and fill the holes. In our case the ‘mounds’  
180 are the early water masses and the ‘holes’ are the late water masses.

181 For the EMD algorithm, we require a ‘distance’ metric ( $D$ ), which is a matrix whose  $i$ th column  
182 and  $j$ th row ( $d_{ij}$ ) is the cost of moving from the  $i$ th early water mass to the  $j$ th late water mass.

183 The EMD algorithm then estimates  $g$  such that (5) is satisfied and the following total transport  
 184 weighted ‘distance’ travelled is minimized

$$\sum_{j=1}^N \sum_{i=1}^N g_{ij} d_{ij}. \quad (6)$$

185 We use the following distance metric

$$d_{ij} = (T1_i - T2_j)^2 + [a(S1_i - S2_j)]^2 + \delta_{ij} \quad (7)$$

186 where temperature and salinity differences are squared so that long trajectories in  $T$ – $S$  space are  
 187 penalized more than short ones and  $a$  is an arbitrary constant which scales the salinity change  
 188 relative to the temperature change. The intent of  $\delta_{ij}$  is to permit water masses to move across our  
 189 arbitrary geographical boundaries without penalty but at the same time to stop direct exchange  
 190 between geographically disconnected regions, for example between the Southern Ocean and Arctic  
 191 or the tropical Atlantic and tropical Pacific. To achieve this we set  $\delta_{ij} = 0$  where the  $i$ th and  $j$ th  
 192 water masses are in the same or adjacent geographical regions and  $\delta_{ij} = \infty$  otherwise. Regions  
 193 which share a meridional boundary are considered adjacent. The Arctic and North Pacific are not  
 194 considered adjacent while the Indian Ocean and equatorial Pacific regions are considered adjacent.

195 We choose the constant  $a$  to be the ratio of a typical haline contraction coefficient to a typical  
 196 thermal expansion coefficient ( $a = \beta_0/\alpha_0 = 4.28$ ). This does not mean that transformations along  
 197 density surfaces are necessarily preferred. The squares in (7) mean that density compensated  
 198 changes in  $T$  and  $S$  are penalized as much as changes of the same magnitude where one of the signs  
 199 is reversed. We have tested the sensitivity of the method to varying  $a$  by a factor of two and found  
 200 only negligible changes in inferred warming (see the Appendix).

201 By moving water from a temperature  $T1_i$  to  $T2_j$ , the transformation  $g_{ij}$  implies warming or  
 202 cooling of a portion of the  $i$ th early water mass, transforming it into a portion of the  $j$ th late

203 water mass. To gain a picture of the net material change within a water mass we add up all the  
 204 warming/cooling necessary to transform the  $i$ th early water mass into all of its destination water  
 205 masses to derive an average material warming rate ( $\dot{T}_i$ ) within each early water mass

$$\dot{T}_i = \frac{1}{V1_i} \sum_{j=1}^N (T2_j - T1_i) g_{ij}. \quad (8)$$

206 which is shown in Fig. S1.

207 We now aim to use  $\dot{T}$  to define a 3D material temperature change variable  $\Delta T_{Material}$ . To do this  
 208 we make the assumption that the warming of a particular water mass occurred evenly (in a volume  
 209 and time weighted sense) over the regions and times during which that water mass existed in the  
 210 early period. E.g. if a particular location was occupied by the  $n$ th water mass for the entire period  
 211 2006 to 2011, then the inferred rate of change of material temperature at that location would have  
 212 been  $\dot{T}_n$ . Likewise, if the  $n$ th water mass occupied that location between 2006 and 2008 and the  
 213  $m$ th water mass existed there between 2009 and 2011, then the rate of change of material heat  
 214 content will be  $(\dot{T}_n + \dot{T}_m)/2$ . More precisely, at every location  $\mathbf{x}$  we define  $T_{Material}$  as

$$\Delta T_{Material}(\mathbf{x}) = \int_{t_1}^{t_2} \sum_{i=1}^N \Pi(T(\mathbf{x}), [T_i^{min}, T_i^{max}]) \Pi(S(\mathbf{x}), [S_i^{min}, S_i^{max}]) \dot{T}_i dt.$$

215 Above,  $\Pi$  is a boxcar function such that  $\Pi(T, [T_1, T_2])=1$  when  $T_1 \leq T < T_2$  and 0 otherwise and  
 216  $t_1$  the start of 2006 and  $t_2$  is the end of 2011.

217 We could equally have attributed warming to each late water mass based on how much heat was  
 218 required to transform the early water masses into the late water mass. We find the above approach  
 219 more intuitive. The difference between maps of material heat content change made using the two  
 220 approaches are well within the uncertainties stated (not shown).

221 We will contrast the inferred material warming at  $\mathbf{x}$  against the total warming  $\Delta T(\mathbf{x}) = T(\mathbf{x}, t_2) -$   
222  $T(\mathbf{x}, t_1)$  with the residual of the two being a redistribution component such that

$$\Delta T_{Material} = \Delta T - \Delta T_{Redistribution} \quad (9)$$

223 In the Appendix we compare results of our method applied to synthetic data from a climate model  
224 simulation to an added heat variable explicitly simulated by the model. We find good agreement  
225 between added heat and our inferred  $\Delta T_{Material}$  and between simulated redistributed heat and  
226 inferred  $\Delta T_{Redistribution}$  when ocean temperature and salinity are fed in as ‘data’ to the method.  
227 The Appendix also explores sensitivity of our results to parameter choices. The uncertainties we  
228 place on OHC change are  $\pm 2$  standard deviations of a bootstrap ensemble, also described in the  
229 Appendix.

230 To produce maps of the total, material and redistributed contributions to the heat content we  
231 multiply the density and heat capacity of sea water by the respective temperature change and  
232 vertically integrate these through the entire water column. Our method also produces a material  
233 salinity change. We leave discussion of those data to future work.

## 234 4. Results

235 Patterns of total OHC change between early and late periods are heterogeneous (Fig. 3A). There  
236 are basin scale patches of decreasing heat content in the western equatorial and tropical Pacific, in  
237 the Pacific sector of the Southern Ocean, in the subtropical south Indian Ocean, and the subpolar  
238 North Atlantic. Warming is seen most strongly in the tropical eastern Pacific, south Atlantic Ocean  
239 and subtropical North Atlantic. These changes are highly sensitive to the specific observation years  
240 chosen and the length of the epochs reflecting the regional timescale of variability associated with  
241 the redistributed component. Uncertainty is far larger than the signal in the majority of regions

242 (stippling in Fig. 3A) and coincident with previously-identified regions of large sea level anomaly  
243 variability (Penduff et al. 2011). However, there are a few regions (e.g. the Southern Ocean and  
244 North Atlantic) where the regional redistributed signal is robust and emerges from the uncertainty  
245 (Fig. 3B).

246 Material heat content change shows a smaller amplitude but more coherent signal than redis-  
247 tributed heat (Figs. 3B and 3C). Material warming is seen across almost the entirety of the globe,  
248 with maxima in the Southern Hemisphere and Atlantic subtropical convergence zones (Maximenko  
249 et al. 2009), consistent with model simulations of passive ocean heat uptake due to anthropogenic  
250 greenhouse warming (Gregory et al. 2016). Strikingly however, the uncertainty in material heat  
251 content change is far smaller than that of total OHC change (stippling in Fig. 3C). This suggests  
252 that heat was added to and distributed within the ocean persistently over the Argo period and that  
253 this warming is not an artifact of a particularly warm year or years.

254 Zonally integrating the net OHC change reveals a signal of roughly the same magnitude as its  
255 uncertainty at all latitudes (Fig. 4A). Zonally integrated redistributed heat likewise has a small  
256 signal to uncertainty ratio except in the Southern Ocean (Fig. 4A). Accumulating the redistributed  
257 heat contribution from north to south gives the meridional heat transport due to redistribution.  
258 Broadly, heat is redistributed from north to south with a southward cross equatorial transport of  $73$   
259  $\pm 60$  TW between the two epochs (Fig. 4C).

260 Material heat content change is larger than its uncertainty at most latitudes and shows a peak at  
261  $35^{\circ}\text{S}$ ,  $15^{\circ}\text{N}$  and  $35^{\circ}\text{N}$ . The material heat content change peaks at  $35^{\circ}\text{S}$  and  $35^{\circ}\text{N}$  are collocated  
262 with climatological wind stress curl minima, which drive Ekman downwelling.

263 Table 1 shows material, redistributed and total heat content changes by ocean basin. Material  
264 heat content change is distributed among the Indian, South Pacific and South Atlantic basins  
265 approximately according to their area. However, the North Atlantic stores close to 25% of the

266 global ocean's material heat content change despite representing less than 12% of its area (Table  
267 1). An outsized role for the Atlantic and Southern Ocean in storing material heat content change in  
268 the climate system has also been foreseen in numerical modeling studies (Lee et al. 2011; Kuhlbrodt  
269 and Gregory 2012).

270 We identify robust redistributed warming signals in the sub-tropical North Atlantic and Southern  
271 Ocean. Warming in the sub-tropical North Atlantic is compensated by cooling in the sub-polar  
272 North Atlantic consistent with a  $40 \pm 13$  TW southward transport of heat across  $44^\circ\text{N}$  (Fig. 3C,  
273 Fig. 4C). Warming in the Southern Ocean is far larger and explained by  $118 \pm 50$  PW of southward  
274 heat transport across  $32^\circ\text{S}$ .

## 275 **5. Discussion**

276 Recent anomalous southward heat transport in the North Atlantic has been well documented  
277 and has been attributed to a downturn in the Atlantic Meridional Overturning Circulation (Smeed  
278 et al. 2013; Bryden et al. 2020). Observed heat transport anomalies equate to a downturn in MHT  
279 equivalent to  $-23 \pm 60$  TW for the period 2006-2011 vs 2012-2017 at  $26^\circ\text{N}$  in the Atlantic (see the  
280 Appendix for details of this calculation which is based on data from Bryden et al. 2020) which is  
281 consistent with our estimate of the change in redistribution heat transport of  $-23 \pm 19$  TW (Fig. 4,  
282 uncertainties are  $\pm 2$  standard deviations).

283 The large apparent meridional heat transport we have identified in the Southern Ocean was  
284 previously identified by Roberts et al. (2017) based on the residual of observed OHC change and  
285 estimates of air sea heat fluxes. Their approach captures additional heat in the system where it  
286 is fluxed into the ocean while our approach estimates how that heat is distributed. Nonetheless,  
287 the correspondence between our results and theirs is reassuring and perhaps not surprising if the  
288 redistribution signal is large as both approaches indicate.

289 The approach of Zanna et al. (2019) is more directly comparable to ours. They reconstruct the  
290 passive contribution to ocean warming since 1850 by propagating SST anomalies into the ocean  
291 interior using Green's functions. They compare their inferred passive warming between 1955 and  
292 2016 to the warming observed in situ and find evidence of a large southward redistribution of heat  
293 in the Northern Hemisphere. This may suggest that the southward redistribution of heat inferred by  
294 both Roberts et al. (2017) and this study in the Southern Hemisphere is a more recent occurrence.

## 295 **6. Conclusions**

296 In conclusion we have shown that:

- 297 • Water mass changes between 2006-2011 and 2012-2017 can be interpreted in terms of a  
298 material warming across the globe, concentrated most strongly in the Southern Ocean and  
299 North Atlantic, consistent with simulations of the addition of heat into the ocean due to green  
300 house forcing;
- 301 • The majority of the pattern of ocean heat content change over that period can be explained by  
302 a redistribution of existing water masses within the ocean;
- 303 • The inferred redistribution indicates a downturn in northward meridional heat transport into  
304 the sub-polar North Atlantic of  $40 \pm 13$  TW and an anomalous southward heat transport into  
305 the Southern Ocean of  $118 \pm 50$  TW.

306 The material warming signal we have inferred is generally weaker than redistribution, but the  
307 signal is far less sensitive to changes in the years over which the analysis was carried out. This  
308 suggests material warming may be giving a robust indication of slow thermodynamic changes in  
309 the ocean, potentially as a result of anthropogenic forcing. This would be remarkable since there  
310 are only 6 years between the centre of the early and late periods we have considered.

311 We expect the strength of the material warming signal to increase into the future as the ocean  
312 warms. However since the redistribution signal is so large, circulation changes and variability must  
313 be understood if near term regional sea level change is to be projected accurately.

314 *Acknowledgments.* We would like to acknowledge the UK Met Office’s Hadley Centre for main-  
315 taining the EN4 data set used here and Professors O. Pele and M. Werman for developing and  
316 making available their Earth Mover Distance code. We thank John Church, Richard Sanders and  
317 Lijing Cheng for helpful suggestions regarding this manuscript.

320 also supported by European Union Horizon 2020 grant 817578 (TRIATLAS). JG was supported  
321 by Natural Environment Research Council grants NE/P019099/1 (TICTOC) and NE/R000727/1  
322 (UK-FAFMIP).

323 *Data availability statement.* Analyzed temperature and salinity data used in  
324 this study was from EN4 (Good et al. 2013) and is publicly available at  
325 <https://www.metoffice.gov.uk/hadobs/en4/download-en4-2-1.html>.

326 Code used to convert EN4 in-situ temperature and practical salinity fields to con-  
327 servative temperature and absolute salinity were from the Gibbs Sea-Water Oceano-  
328 graphic Toolbox available at <http://www.teos-10.org/software.htm#1>. Code which im-  
329 plements the methods described in the Methods Section are available at drop-  
330 box.com/sh/wl1ry8lbf6m56mv/AABIbWi5blAucyzEQQWXF2oVa?dl=0 and will be made avail-  
331 able in a stable online repository before publication. The aforementioned code includes FastEMD  
332 (Pele and Werman 2008, 2009) software available at <http://www.cs.huji.ac.il/~ofirpele/FastEMD/>.

## APPENDIX

334 Accuracy of the warming estimates we have produced rely on the following assumptions:

- 335 1. The mapping from transformations in  $T - S$  space for each region to local changes in geo-  
336 graphical space is accurate;
- 337 2. The ‘minimum transformation’ inferred using the EMD algorithm, including our choice of  
338 distance metric, accurately estimates the net thermodynamic transformation;
- 339 3. The resolution of our T-S grid is sufficiently fine to capture relevant water masses; and
- 340 4. The density of observations and the procedure used to map them onto a regular grid is  
341 sufficiently accurate for us to quantify changes in water mass volumes.

342 We investigate the impact of each of these assumptions in the supplementary text. We investigate  
343 1 and 2 using synthetic data from a climate model where ‘added heat’ is explicitly simulated  
344 (Section 1) and we investigate 3 and 4 using sensitivity tests (Section 2 and Section 3). A bootstrap  
345 approach is taken in the latter case to derive uncertainty estimates.

### 346 **A1. Validation using synthetic data**

347 We use synthetic data from the Hadley Centre Climate Model version HadCM3 (Gordon et al.  
348 2000) to validate the method described in the methods section. Specifically, we exploit the con-  
349 figuration used for the Flux Anomaly Forced Model Inter-comparison Project (FAFMIP, Gregory  
350 et al. 2016). We will consider two specific model experiments used by FAFMIP: *piControl*, which  
351 is a reference experiment with no external forcing, and *FAFheat*, where the ocean is warmed by  
352 an imposed surface heat flux.

353 In *FAFheat* ‘added temperature’ ( $T_{added}$ ) and ‘redistributed temperature’ ( $T_{redist}$ ) tracers are  
354 simulated explicitly.  $T_{added}$  is simulated as a passive tracer initialized at zero and forced at the  
355 ocean boundary by the imposed heat flux anomaly.  $T_{redist}$  is simulated, again, as a passive tracer,

356 which is initialized with the true ocean temperature at the start of the perturbation experiment and  
357 does not increase with the imposed heat flux anomaly but continues to respond to all other fluxes of  
358 heat at the sea surface within the coupled climate model. By construction the  $T$  in  $FAFheat$  is the  
359 sum of the  $T_{added}$  and  $T_{redist}$ . Unlike the redistributed heat inferred using our method,  $T_{redist}$  can be  
360 a net non-zero contributor to ocean heat content. This is because in both  $piControl$  and  $FAFheat$   
361 the surface heat flux can vary because of unforced fluctuations which are not constrained to sum  
362 to zero, and in  $FAFheat$  it is modified also due to changes in sea surface temperature, caused by  
363 changes in ocean circulation, arising from buoyancy forcing by the imposed heat perturbation. For  
364 more details of this phenomenon and of FAFMIP in general see Gregory et al. (2016).

365 There are two aspects of our method which we aim to validate using these data: the uncertainty  
366 introduced by 1) projecting an inferred warming signal from temperature and salinity classes (water  
367 masses) to the geographical location of those water masses and 2) using the Earth Mover Distance  
368 Algorithm.

369 The FAFMIP protocol does not describe historical climate change but rather an idealized increase  
370 in ocean heat content as would be expected from a doubling in atmospheric CO<sub>2</sub>. Our observational  
371 record is centered on the beginning of 2012 when the global atmospheric CO<sub>2</sub> concentration reached  
372 392 parts per million (Conway et al. 1994), which is approximately 40% above pre-industrial levels  
373 of approximately 280 parts per million. Although no comparison can be perfect, we consider this  
374 reasonable motivation to choose years 35-46 of the FAFMIP experiments to test our method.

375 HadCM3 conserves potential temperature and a salinity variable initialized based on observed  
376 practical salinity, so we use these to define temperature and salinity respectively for the purposes  
377 of defining water masses in this analysis.

378 *a. Validation of the water mass based projection*

379 Fig. A4 a shows the column integral of the added heat tracer for years 41 to 46 for the HadCM3  
380 *FAFheat* experiment (the tracer is represented in Kelvin but is here converted to more familiar  
381 W/m<sup>2</sup> by multiplying by the heat capacity and density and dividing by 43 years). As was done to  
382 the EN4 data, we selected water mass bins using a quadtree approach. Fig. A4b shows column  
383 integrated added heat change between years 41-46, but in this case where the added heat tracer is  
384 first averaged within each water mass within each of the 9 geographical regions, then projected back  
385 into the location of those water masses. What this projection amounts to is simply homogenizing the  
386 added heat tracer within each water mass in each region. If added heat change varies substantially  
387 within a water mass this method will smooth out those variations. In the zonal mean (Fig. A4c)  
388 the re-projected added heat has an RMS error of 0.5 TW/°lat.

389 *b. Validation of the Earth Mover Distance based method*

390 We will test our method in the following three scenarios:

- 391 1. Added heat only - heat is added to the ocean and water masses are not redistributed;
- 392 2. Redistribution only – no heat is added and water masses are redistributed;
- 393 3. Added and redistributed heat – Heat is added and water masses are redistributed.

394 Table A1 details the way data from *piControl* and *FAFheat* are used for these scenarios.

395 1) SCENARIO 1

396 In this scenario there is no explicit ‘redistribution’ signal in the model data. The purpose of this  
397 validation is to see how much of the change is attributed to material heat content change using our  
398 water mass change approach. In the zonal mean (Fig. A4A) the difference between the simulated

399 and inferred added heat (which is precisely the inferred redistributed heat) has an RMS of 1.8  
400 TW/°lat.

## 401 2) SCENARIO 2

402 In this scenario there is no explicit ‘added heat’ signal in the model data. This is simply a climate  
403 control run with no variations in forcing (solar, aerosol etc). There is, however, some very small  
404 changes in ocean heat uptake due to natural variability in the fluxes of heat at the air-sea interface.  
405 The purpose of this validation is to see how much of the change is attributed to our redistributed  
406 heat using our water mass change approach. In the zonal mean (Fig. A4B) the difference between  
407 the simulated heat content change and the inferred redistributed heat (which is precisely the inferred  
408 added heat) has an RMS of 0.4 TW/°lat.

## 409 3) SCENARIO 3

410 In this scenario there is both an explicit ‘added heat’ signal in the model data and the model  
411 redistributes heat in response to both natural variability and the imposed warming. Despite the  
412 inclusion of a non-zero global mean net surface heat flux in FAFMIP redistributed heat (as described  
413 above), it is instructive to see how well our material and redistributed heat estimates compare to  
414 the directly simulated added and redistributed heat variables. In the zonal mean (Fig. A4C)  
415 the difference between both the simulated FAFMIP added heat content and the inferred material  
416 heat content change and between the simulated FAFMIP redistributed heat and our water mass  
417 based redistributed heat, has an RMS of 2.4 TW/°lat. We emphasize that this difference should not  
418 necessarily be directly attributed to an inaccuracy in our method considering the differing meanings  
419 of redistributed heat between the model simulations and our method. Broadly we consider the  
420 stated differences between directly simulated and inferred changes to be acceptable. We made no

421 attempt to tune method parameters to optimize correspondence with the simulated variables, but  
422 this could be pursued in future.

## 423 **A2. Parameter sensitivity**

424 Here we test the sensitivity of the results, in particular the zonally integrated added heat, to  
425 parameter choices within the water mass method.

426 The two choices were: i) the choice of relative penalty on temperature versus salinity changes  
427 (i.e. parameter ‘a’) and ii) the number of water masses in T-S space used to represent the early and  
428 late ocean states. We discuss sensitivity to these choices here.

429 The reference case for a is the ratio of a constant haline contraction coefficient ( $\beta_0 = 7.55 \times 10^{-4}$   
430  $\text{kg} / (\text{g}/\text{kg}) \text{ m}^3$ ) to a constant thermal expansion coefficient ( $\alpha_0 = 1.76 \times 10^{-4} \text{ kg} / \text{K m}^3$ ; i.e.  $a_0$   
431  $= \alpha_0 / \beta_0 = 4.3\text{K} / (\text{g} / \text{kg})$ ). This choice implies a transformation by 1g/kg in absolute salinity  
432 is penalized equivalently to a transformation of 4.3K in temperature. A larger a will cause the  
433 method to favor transformation along the S axis and a smaller a will favor transformation along the  
434 T axis. We test the method in the following cases:  $a = a_0$ ;  $a_0/2$  and  $2*a_0$  (Fig. A4A) and find RMS  
435 differences of 0.3 TW / °lat between the reference case and the doubling and halving cases.

436 In terms of  $T - S$  resolution, our reference case has a minimum  $T - S$  bin size of 0.2 g / kg and  
437 0.4 K. Using the quadtree method the grid is refined until either this resolution is achieved or the  
438 volume within a particular bin falls below  $62 \times 10^{12} \text{ m}^3$ . We test the sensitivity of this choice by  
439 both refining and coarsening the resolution by a factor of two in both the salinity and temperature  
440 dimensions and reducing the volume threshold by a factor of four also.

441 Decreasing the resolution induces an RMS change in estimated zonally averaged OHC of 0.5  
442 TW/°lat and increasing the resolution induces an RMS change of 0.4 TW/°lat (Fig. A4B).

### 443 **A3. Robustness of 21st Century trend**

444 To quantify the sensitivity of our trend results to the time period chosen and the specific obser-  
445 vations made and mapped in that period, we carry out a bootstrap calculation. Our aim here is  
446 not to determine how accurate our trend is, but rather to determine how representative it is of time  
447 period as a whole or if specific years strongly influence the result.

448 We chose to subsample the data by including and excluding entire years from the analysis. Six  
449 years are used for the early (2006-2011) and late (2012-2017) periods of our analysis of EN4. We  
450 therefore considered all possible permutations of the numbers one to six and re-ran our analysis of  
451 EN4 subsampling the years corresponding to those six numbers. For example, in the case [1, 3, 3,  
452 4, 5, 6] the ‘early period’ data was replaced with the years 2006, 2008 repeated twice, 2009, 2010  
453 and 2011 and the ‘late period’ with 2012, 2014 repeated twice, 2015, 2016 and 2017.

454 There are 46656 uniquely ordered permutations of the numbers one to six when repetition is  
455 permitted. Since the calculation is insensitive to the order of the six years for either the early or  
456 late period, in practice we only need to consider the 462 unique permutations (ignoring order) and  
457 weight each by its frequency in the larger set of ordered permutations.

458 Fig. 3 shows the mean while Fig. A4 shows the standard deviation of the bootstrap ensemble.  
459 Plus and minus two standard deviations of the spread in estimates of zonally averaged heat content  
460 change are shown in Fig. 4. Since these error estimates are generally larger than our other parameter  
461 sensitivity tests, we use them as our formal uncertainties throughout the main text.

### 462 **A4. Comparison with Atlantic meridional heat transport trend at 26°N**

463 We will compare our estimate of the contribution of redistribution to MHT north of 26°N in the  
464 Atlantic (Fig. 4C) with data reported by Bryden et al. (2020) (Tab. A4). MHT relates to the rate of  
465 change of OHC. That is  $MHT = \partial OHC / \partial t$ . The difference in OHC between two year (for example

466 2006 and 2012) relates to MHT via

$$\int_{2006}^{2012} MHT dt = OHC(2012) - OHC(2006). \quad (A1)$$

467 We have considered the difference in OHC between two 6 year periods (2006-2011 versus 2012-  
468 2017). Hence our OHC change and MHT are related via

$$\begin{aligned} \left( \int_{t_0}^{t_0+\Delta t} OHC(t) dt - \int_{t_0-\Delta t}^{t_0} OHC(t) dt \right) = \\ \int_{t_0}^{t_0+\Delta t} (OHC(t) - OHC(t - \Delta t)) dt = \\ \int_{t_0}^{t_0+\Delta t} \int_{t-\Delta t}^t MHT(t') dt' dt \end{aligned} \quad (A2)$$

469 where  $t_0$  is midnight on the 31st December 2012 and  $\Delta t$  is 6 years. In practice we have averages of  
470 MHT covering April-March (see table A4), we approximate (A2) using 6 year running means of  
471 MHT then averaging these between 2009-2010 and 2014-2015. Our uncertainties are  $\pm$  two times  
472 the standard deviation of the 6-year running means.

567 **LIST OF TABLES**

568 **Table 1.** Heat content change by ocean basin in TW. Estimates are based on differences  
569 between the periods 2006-2011 and 2012-2017 inclusive. Uncertainties are  $\pm$   
570 two standard deviations. The Southern Ocean is defined as the entire ocean  
571 south of  $32^\circ\text{S}$ . The South Pacific, South Atlantic and Indian Ocean estimates  
572 exclude the ocean south of  $32^\circ\text{S}$ . The North Atlantic is split into a region south  
573 and a region north of  $44^\circ\text{N}$ . The later includes the Arctic Ocean. . . . . 29

574 **Table A1.** Summary of data used for three validation scenarios.  $T_{ref}$  and  $S_{ref}$  are the  
575 temperatures and salinities from the *piControl* experiment respectively.  $T_{added}$   
576 is the added heat variable and  $T_{redist}$  is the redistributed heat variable from  
577 the *FAFheat* experiment.  $S_{heat}$  is the salinity variable from the *FAFheat*  
578 experiment. The numbers in brackets are the experiment years chosen (e.g.  
579  $T_{ref}(41-46)$  is temperature from years 41 to 46 of the piControl experiment). . . . . 30

580 **Table A2.** Atlantic meridional heat transport (MHT, in PW) at  $26^\circ\text{N}$  (Bryden et al. 2020),  
581 MHT anomaly relative to 2006-2017 and 6-year running mean MHT. The mean  
582 of 6-year running means is relevant to the difference in OHC between 2006-2011  
583 and 2012-2017. . . . . 31

584 TABLE 1. Heat content change by ocean basin in TW. Estimates are based on differences between the periods  
 585 2006-2011 and 2012-2017 inclusive. Uncertainties are  $\pm$  two standard deviations. The Southern Ocean is defined  
 586 as the entire ocean south of 32°S. The South Pacific, South Atlantic and Indian Ocean estimates exclude the  
 587 ocean south of 32°S. The North Atlantic is split into a region south and a region north of 44°N. The later includes  
 588 the Arctic Ocean.

	Material	Redistributed	Total
Southern Ocean	90 $\pm$ 18	118 $\pm$ 50	208 $\pm$ 63
South Pacific	53 $\pm$ 16	-26 $\pm$ 22	28 $\pm$ 22
North Pacific	82 $\pm$ 25	-61 $\pm$ 55	21 $\pm$ 54
Indian Ocean	45 $\pm$ 10	-13 $\pm$ 25	32 $\pm$ 30
South Atlantic	34 $\pm$ 11	6 $\pm$ 7	40 $\pm$ 7
North Atlantic (< 44°N)	75 $\pm$ 33	20 $\pm$ 17	95 $\pm$ 46
North Atlantic (> 44°N)	19 $\pm$ 6	-40 $\pm$ 13	-20 $\pm$ 16
Global Ocean	398 $\pm$ 81	0	398 $\pm$ 81

589 Table A1. Summary of data used for three validation scenarios.  $T_{ref}$  and  $S_{ref}$  are the temperatures and  
590 salinities from the *piControl* experiment respectively.  $T_{added}$  is the added heat variable and  $T_{redist}$  is the  
591 redistributed heat variable from the *FAFheat* experiment.  $S_{heat}$  is the salinity variable from the *FAFheat*  
592 experiment. The numbers in brackets are the experiment years chosen (e.g.  $T_{ref}(41-46)$  is temperature from  
593 years 41 to 46 of the piControl experiment).

Scenario	Early period	Late period
1	$T = T_{ref}(41-46),$ $S = S_{ref}(41-46)$	$T = T_{ref}(41-46)+T_{added}(41-46)$ $S = S_{ref}(41-46)$
2	$T = T_{ref}(35-40)$ $S = S_{ref}(35-40)$	$T = T_{ref}(41-46)$ $S = S_{ref}(41-46)$
3	$T = T_{added}(35-40)+T_{redist}(35-40)$ $S = S_{ref}(35-40)$	$T = T_{added}(41-46)+T_{redist}(41-46)$ $S = S_{heat}(41-46)$

595 Table A2. Atlantic meridional heat transport (MHT, in PW) at 26°N (Bryden et al. 2020), MHT anomaly  
 596 relative to 2006-2017 and 6-year running mean MHT. The mean of 6-year running means is relevant to the  
 597 difference in OHC between 2006-2011 and 2012-2017.

Year	MHT	Anomaly	6-year mean

## LIST OF FIGURES

599		
600	<b>Fig. 1.</b>	Portrait of changing ocean water masses. A: Inventory of ocean volume in conservative temperature versus absolute salinity coordinates (mean of 2006 to 2017 inclusive). B: Change in water mass volume between the early half and late half of the period divided by the six years ( $Sv = 106m^3/s$ ). According to water mass theory, changes in air-sea heat and fresh water fluxes and/or changes in rates of diffusion are required for these changes to occur. . . . . 34
601		
602		
603		
604		
605	<b>Fig. 2.</b>	Grey lines show conservative temperature, $T$ , and absolute salinity, $S$ , bounds of each water mass (or ‘bin’) generated by the quadtree method for each geographical region. The average $T$ and $S$ of the water found within each bin is shown by the location of each marker and the volume is represented by the color scale ( $\log_{10}(m^3)$ ). Inventories and mean $T$ and $S$ values represent the entire period (2006-2017 inclusive). Inset panels show masks associated with each geographical region. . . . . 35
606		
607		
608		
609		
610		
611	<b>Fig. 3.</b>	Heterogeneous pattern of total and redistributed heat content change contrast against robust material heat content change. A: Change in depth integrated ocean heat content between years 2006-2011 and 2012-2017 inclusive. B: Inferred redistributed heat and C: Inferred material heat content change based on changing water masses for the same period. Regions where the magnitude of the signal is less significant (less than two standard deviations of a bootstrap ensemble) are stippled. . . . . 36
612		
613		
614		
615		
616		
617	<b>Fig. 4.</b>	Material heat content change is accumulating in the tropics and sub-tropics existing heat is being redistributed southward. A: Total heat content change (grey) redistribution contribution (blue) and material contribution (red). B: Contributions to material heat content change from the Indian (green), Pacific (orange) and Atlantic (yellow) Oceans. C: Meridional heat transport due to redistribution in the Southern Ocean (blue), Atlantic (cyan) and Indian plus Pacific Oceans (magenta). Estimates are bootstrap ensemble means with shading representing $\pm$ two standard deviations. . . . . 37
618		
619		
620		
621		
622		
623		
624	<b>Fig. S1.</b>	Each marker shows $\Delta T_{material}$ , the average warming required for each early water mass in order to transform them into the set of late water masses. . . . . 38
625		
626	<b>Fig. S2.</b>	A: Directly simulated added heat by the FAFheat experiment averaged over years 41-46 of the experiment. B: Inferred added heat when the same FAFheat data is first homogenized in water masses (bins in temperature-salinity coordinates) then remapped into the locations of those water masses over the same period. C: Comparison of the zonal integration of the two quantities shown in A and B. . . . . 39
627		
628		
629		
630		
631	<b>Fig. S3.</b>	A: Zonally integrated simulated added heat (solid, red) and inferred material heat content change (dashed, red) based on our water mass method for years 41-46 of the <i>FAFheat</i> experiment comparing the simulation with and without added heat. B: Zonally integrated simulated heat content change (solid, blue) and inferred redistributed heat (dashed, blue) based on our water mass method comparing years 35-40 and 41-46 of the <i>piControl</i> experiment. C: Zonally integrated simulated added heat (solid, red) and redistributed heat (blue, solid) in the <i>FAFheat</i> experiment and inferred material heat content change (dashed, red) and redistributed heat (dashed, blue) based on our water mass method applied the model data. . . . . 40

637		
638		
639	<b>Fig. S4.</b>	A: Zonally integrated inferred material heat content change for cases where the parameter $a$ is set at a reference value of $a_0 = \alpha_0 / \beta_0 = 4.3K/(g/kg)$ (black) and then reduced (red) and increased (blue) by a factor of two. B: Zonally integrated inferred material heat content change for cases where the $T - S$ bins are shrunk using a quadtree method until they either contain a volume of sea water less than $62 \times 10^{12}m^3$ or have a bin size of $0.4^\circ C$ by $0.2 g/kg$
640		
641		
642		
643		

644 (black). Cases where the minimum volume is  $15.5 \times 10^{12} \text{ m}^3$  and the minimum bin size is  
645  $0.2^\circ\text{C}$  by  $0.1\text{g/kg}$  (blue) and where the minimum volume is  $248 \times 10^{12} \text{ m}^3$  and the minimum  
646 bin size is  $0.8^\circ\text{C}$  by  $0.4\text{g/kg}$  (red). . . . . 41

647 **Fig. S5.** A: One standard deviation of the heat content change inferred based on subsampling ‘early’  
648 and ‘late’ years of the EN4 data set. One standard deviation of the ensemble of inferred  
649 material heat content change (B) and redistributed heat (C) based on our water mass method  
650 applied to the same subsampled data as in A. . . . . 42

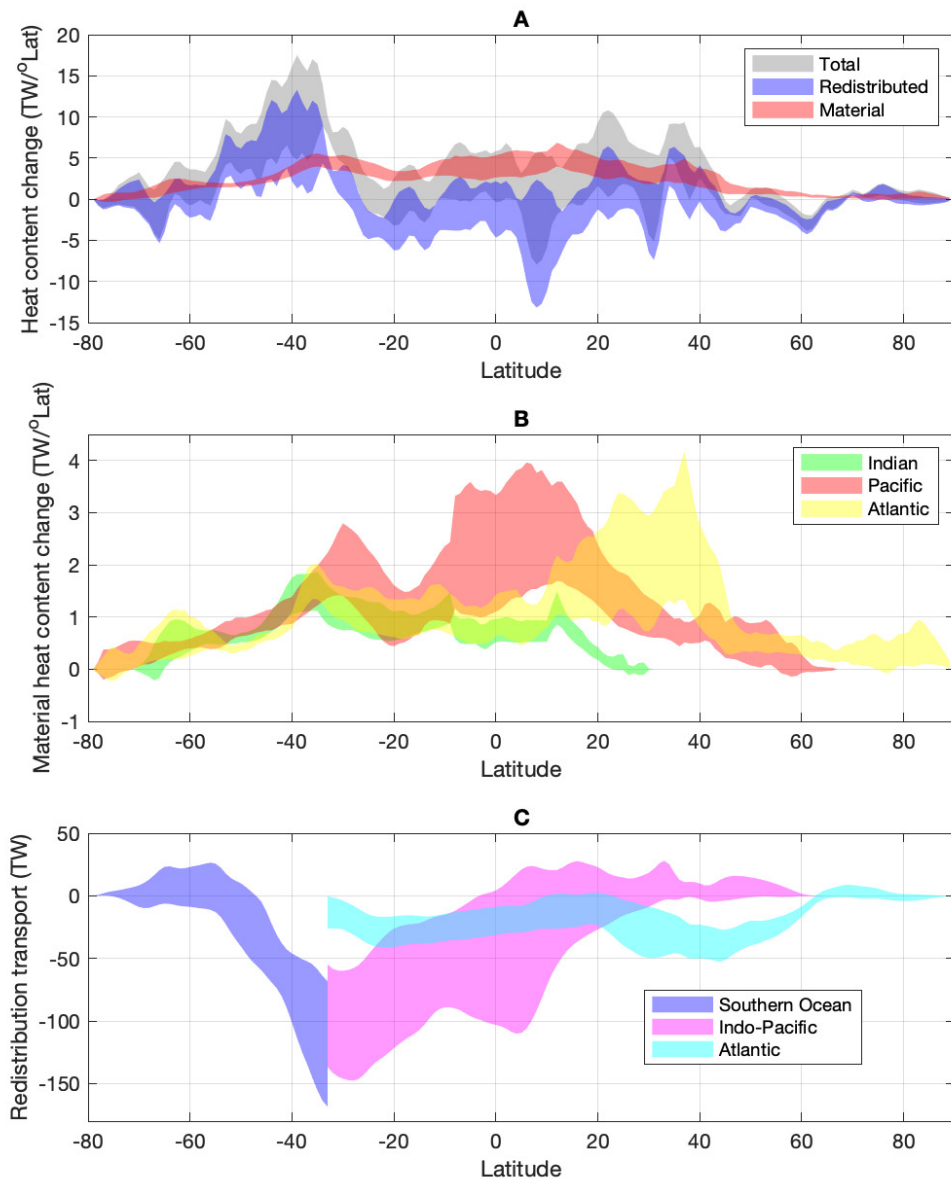

651 FIG. 1. Portrait of changing ocean water masses. A: Inventory of ocean volume in conservative temperature  
 652 versus absolute salinity coordinates (mean of 2006 to 2017 inclusive). B: Change in water mass volume between  
 653 the early half and late half of the period divided by the six years ( $\text{Sv} = 106\text{m}^3/\text{s}$ ). According to water mass theory,  
 654 changes in air-sea heat and fresh water fluxes and/or changes in rates of diffusion are required for these changes  
 655 to occur.

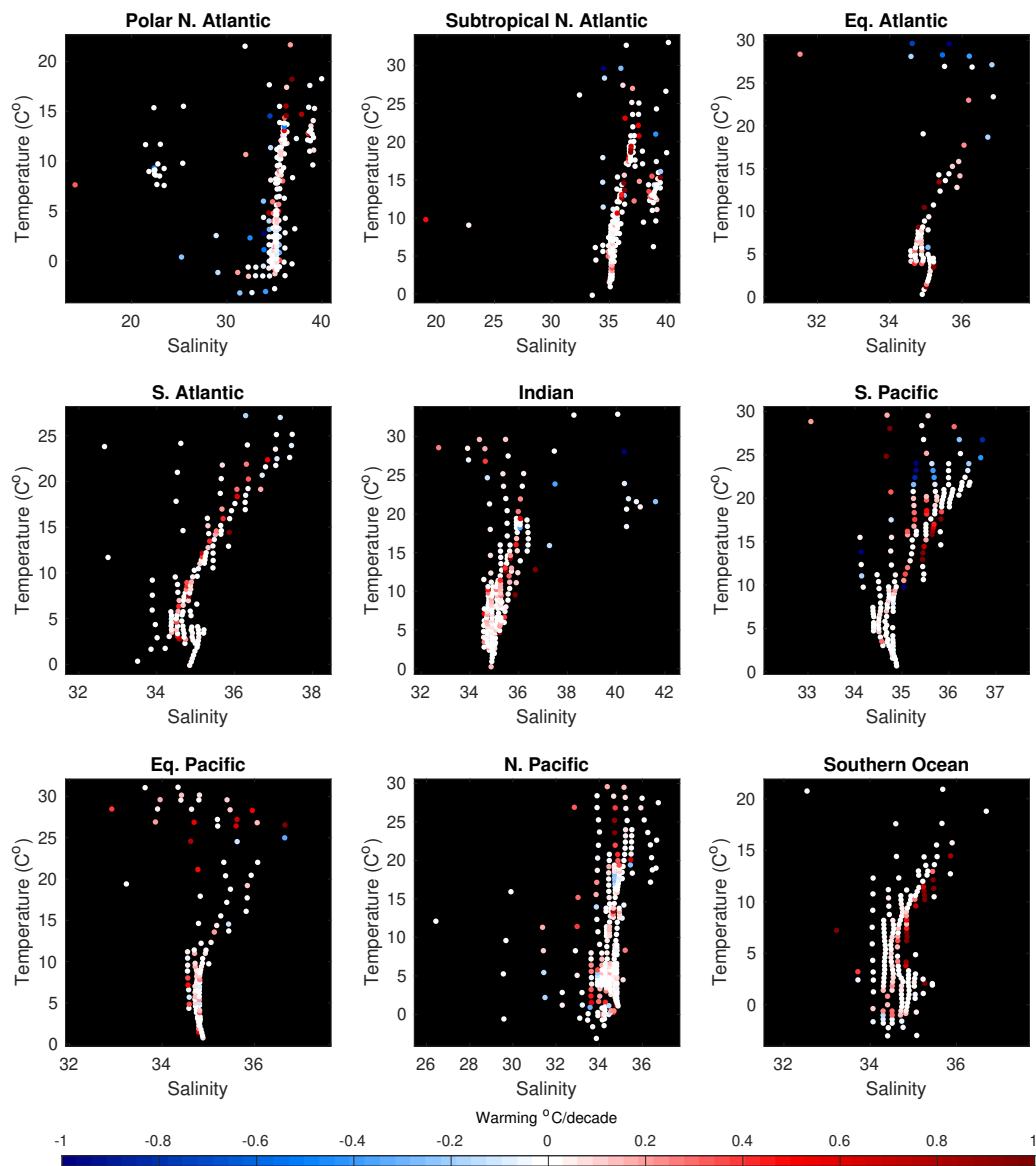

656 FIG. 2. Grey lines show conservative temperature,  $T$ , and absolute salinity,  $S$ , bounds of each water mass  
 657 (or ‘bin’) generated by the quadtree method for each geographical region. The average  $T$  and  $S$  of the water  
 658 found within each bin is shown by the location of each marker and the volume is represented by the color scale  
 659 ( $\log_{10}(\text{m}^3)$ ). Inventories and mean  $T$  and  $S$  values represent the entire period (2006–2017 inclusive). Inset panels  
 660 show masks associated with each geographical region.

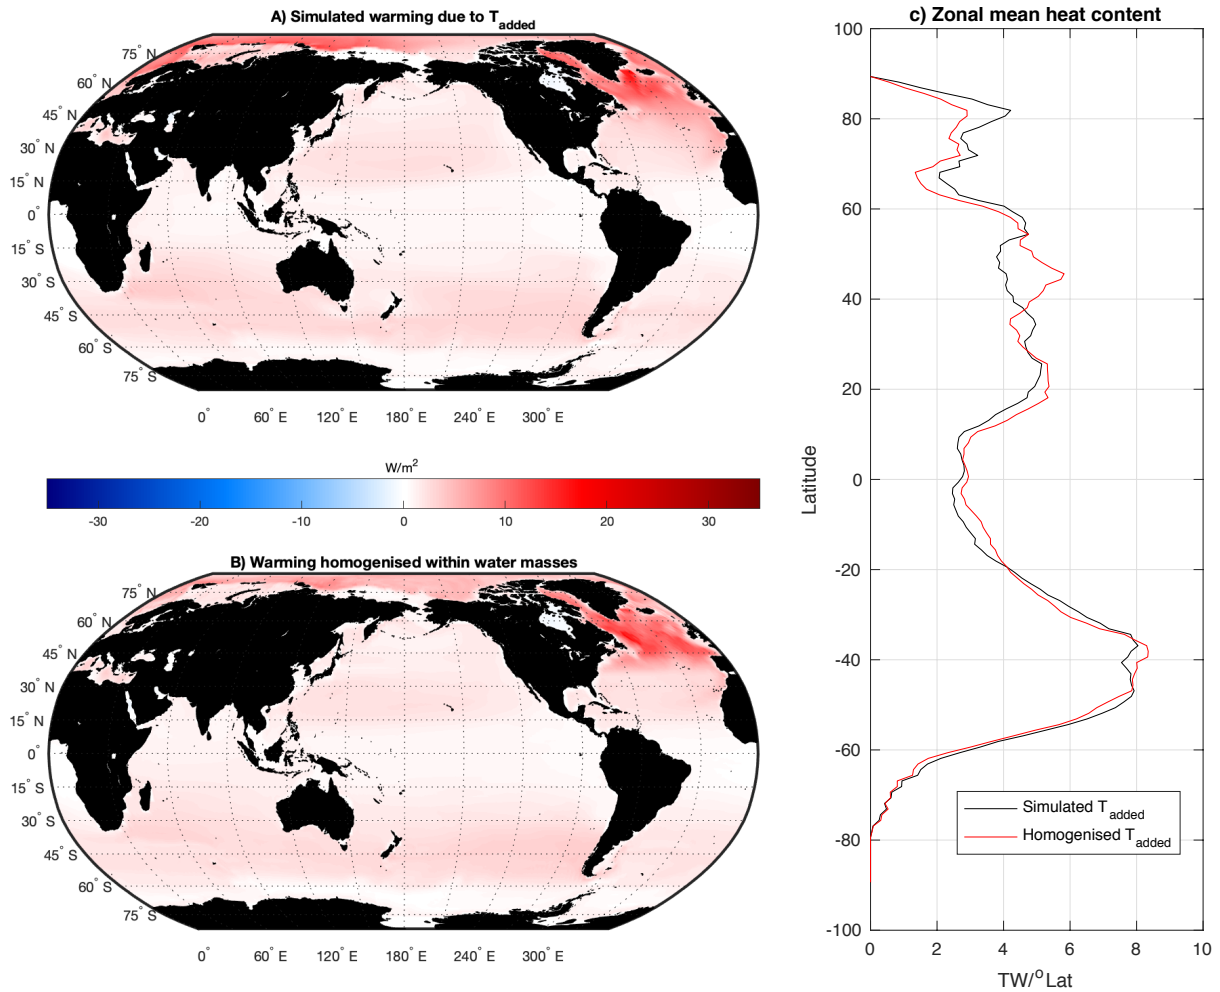

661 FIG. 3. Heterogeneous pattern of total and redistributed heat content change contrast against robust material  
 662 heat content change. A: Change in depth integrated ocean heat content between years 2006-2011 and 2012-2017  
 663 inclusive. B: Inferred redistributed heat and C: Inferred material heat content change based on changing water  
 664 masses for the same period. Regions where the magnitude of the signal is less significant (less than two standard  
 665 deviations of a bootstrap ensemble) are stippled.

666 FIG. 4. Material heat content change is accumulating in the tropics and sub-tropics existing heat is being  
 667 redistributed southward. A: Total heat content change (grey) redistribution contribution (blue) and material  
 668 contribution (red). B: Contributions to material heat content change from the Indian (green), Pacific (orange)  
 669 and Atlantic (yellow) Oceans. C: Meridional heat transport due to redistribution in the Southern Ocean (blue),  
 670 Atlantic (cyan) and Indian plus Pacific Oceans (magenta). Estimates are bootstrap ensemble means with shading  
 671 representing  $\pm$  two standard deviations.

672 Fig. S1. Each marker shows  $\Delta T_{material}$ , the average warming required for each early water mass in order to  
 673 transform them into the set of late water masses.

674 Fig. S2. A: Directly simulated added heat by the FAFheat experiment averaged over years 41-46 of the  
 675 experiment. B: Inferred added heat when the same FAFheat data is first homogenized in water masses (bins in  
 676 temperature-salinity coordinates) then remapped into the locations of those water masses over the same period.  
 677 C: Comparison of the zonal integration of the two quantities shown in A and B.

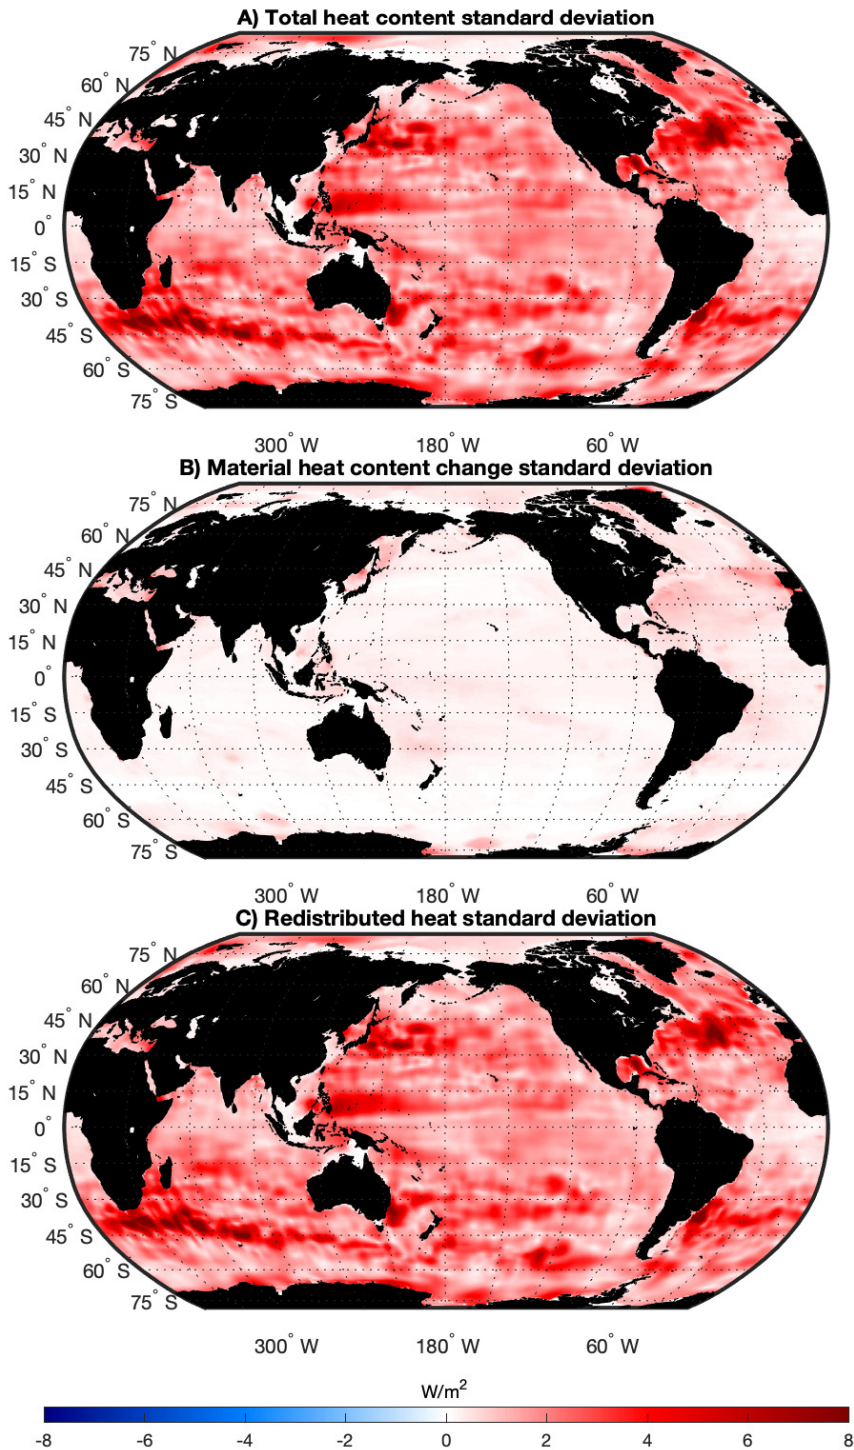

678 Fig. S3. A: Zonally integrated simulated added heat (solid, red) and inferred material heat content change  
 679 (dashed, red) based on our water mass method for years 41-46 of the *FAFheat* experiment comparing the  
 680 simulation with and without added heat. B: Zonally integrated simulated heat content change (solid, blue) and  
 681 inferred redistributed heat (dashed, blue) based on our water mass method comparing years 35-40 and 41-46 of  
 682 the *piControl* experiment. C: Zonally integrated simulated added heat (solid, red) and redistributed heat (blue,  
 683 solid) in the *FAFheat* experiment and inferred material heat content change (dashed, red) and redistributed heat  
 684 (dashed, blue) based on our water mass method applied the model data.

685 Fig. S4. A: Zonally integrated inferred material heat content change for cases where the parameter  $a$  is set at  
 686 a reference value of  $a_0=\alpha_0/\beta_0 = 4.3\text{K}/(\text{g}/\text{kg})$  (black) and then reduced (red) and increased (blue) by a factor of  
 687 two. B: Zonally integrated inferred material heat content change for cases where the  $T - S$  bins are shrunk using  
 688 a quadtree method until they either contain a volume of sea water less than  $62 \times 10^{12}\text{m}^3$  or have a bin size of  
 689  $0.4^\circ\text{C}$  by  $0.2 \text{ g}/\text{kg}$  (black). Cases where the minimum volume is  $15.5 \times 10^{12} \text{ m}^3$  and the minimum bin size is  
 690  $0.2^\circ\text{C}$  by  $0.1\text{g}/\text{kg}$  (blue) and where the minimum volume is  $248 \times 10^{12} \text{ m}^3$  and the minimum bin size is  $0.8^\circ\text{C}$   
 691 by  $0.4\text{g}/\text{kg}$  (red).

692 Fig. S5. A: One standard deviation of the heat content change inferred based on subsampling ‘early’ and ‘late’  
 693 years of the EN4 data set. One standard deviation of the ensemble of inferred material heat content change (B)  
 694 and redistributed heat (C) based on our water mass method applied to the same subsampled data as in A.
