21 **Key Points:**

- 22 • Airborne energy of an underground blast decays exponentially with scaled depth
23 and is in agreement with previous measurements.
24 • Multiple subsurface explosions, properly timed, can break the surface from scaled
25 depths previously thought to be contained in the ground.
26 • Crater sizes correlate with measured seismo-acoustic and high-frequency atmo-
27 spheric signals.

28 **Abstract**

29 Blasting experiments were performed that investigate multiple explosions that occur in
 30 quick succession in the ground and their effects on host material and atmosphere. Such
 31 processes are known to occur during volcanic eruptions at various depths, lateral loca-
 32 tions, and energies. The experiments follow a multi-instrument approach in order to ob-
 33 serve phenomena in the atmosphere and in the ground, and measure the respective en-
 34 ergy partitioning. The experiments show significant coupling of atmospheric (acoustic)-
 35 and ground (seismic) signal over a large range of (scaled) distances (30–330 m, $1\text{--}10\text{ m J}^{-1/3}$).
 36 The distribution of ejected material strongly depends on the sequence of how the explo-
 37 sions occur. The overall crater sizes are in the expected range of a maximum size for many
 38 explosions and a minimum for one explosion at a given lateral location. The experiments
 39 also show that peak atmospheric over-pressure decays exponentially with scaled depth
 40 at a rate of $\bar{d}_0 = 6.47 \times 10^{-4} \text{ m J}^{-1/3}$; at a scaled explosion depth of $4 \times 10^3 \text{ m J}^{-1/3}$
 41 ca. 1% of the blast energy is responsible for the formation of the atmospheric pressure
 42 pulse; at a more shallow scaled depth of $2.75 \times 10^{-3} \text{ m J}^{-1/3}$ this ratio lies at ca. 5.5–
 43 7.5%. A first order consideration of seismic energy estimates the sum of radiated airborne
 44 and seismic energy to be up to 20% of blast energy.

45 **Plain Language Summary**

46 Blasting experiments using six successive explosions were performed in four differ-
 47 ent geometrical setups (linear and triangular). The experiments were monitored by geo-
 48 physical equipment which allows to measure explosive energy, and how much of that en-
 49 ergy goes to the surface. The experiments help to understand volcanic and other sub-
 50 surface explosive processes. Exact measurements of the resulting craters, together with
 51 known explosive energies allow the interpretation of real volcanic craters. The experi-
 52 mental results show initial time developments of crater sizes, which occurs on the order
 53 of one second for crater sizes of the order of one meter. Up to 8% of the explosion’s en-
 54 ergy was detected as airborne signal. Up to 20% of the explosion’s energy was detected
 55 as seismic (elastic) energy in the ground.

1 Introduction

Volcanic activity causes subsurface explosions at various depths that can have severe consequences for its environment. Explosions can have several causes, but it is possible to evaluate some of their aspects independent from their cause. A sudden, large pressure change propagates at supersonic speed for a certain distance in a medium such as host rock, magma or atmosphere, causing deformation in elastic, plastic and brittle regimes (e.g. Schmurr et al., 2020; Kim & Rodgers, 2016; Bowman et al., 2014; Fee et al., 2013; Taylor et al., 2010; Grady, 1996). Shallow explosions fragment and eject magma, host material or both into the atmosphere and pose danger to the surroundings. Deeper explosions (for a given energy release) may be fully contained in the subsurface (Valentine et al., 2014). In case of a subsurface explosion parts of the energy involved will end up in the atmosphere, while some of it will remain in the ground. In volcanic settings explosions may occur as individual events or in rapid succession, at various depths and lateral locations. Characterizing the transition from a fully contained process to near surface is important to estimate the hazards to surroundings and understand some principle mechanisms of the explosion process. Many mechanisms can cause volcanic explosions (Houghton, 2015), but some effects on the surroundings are common to all explosive source mechanisms. For example, all explosive processes mix host material, and shallow explosions eject significant amounts of hot material (Graettinger et al., 2015). Subsurface explosions produce crater structures, that are characteristic for the blast process’s energy and location (Valentine et al., 2014).

In natural settings, explosive volcanic blasts and processes are often monitored using multiple techniques, including seismic and infrasound observation and video recordings at normal and high speeds (Gaudin et al., 2016; Matoza et al., 2019). Seismoacoustics aims to relate signatures of observed seismic and infrasound waveforms to the source processes generating them. A more controlled process than the poorly constrained natural signals, with known source parameters can help to constrain uncertainties and enable scalability of models.

An explosion—a sudden, rapid change of a material’s volume that it imposes on its surroundings—forces that medium to rapidly compress such that the resulting pressure change does not propagate with the same speed as a smaller pressure change would which is described within the linear acoustic approximation. Larger pressure changes cause adiabatic heating in air which locally increases the propagation speed and can lead to dramatic steepening of an initially smooth pressure wave into a discontinuity—a shock (Garcés et al., 2013; Muhlestein et al., 2012; Crighton & Scott, 1979). In an isentropic approximation (reversible process at constant entropy) a shock pulse has characteristic properties such as amplitude and duration that scale with the explosion’s energy and the density of the medium in which the pulse travels (Kinney & Graham, 1985).

Scaling properties enable the establishment of phenomenological regimes that depend on scaled parameters, such as a scaled length. For example, for the depth d of a subsurface explosion, a scaled depth can be defined by

$$\bar{d} = \frac{d}{E_b^{1/3}} \quad , \quad (1)$$

where E_b is the blast’s energy (Holsapple & Schmidt, 1980; Sonder et al., 2015). Using this method blasts of any energy may be categorized into deep, intermediate and shallow blasts. Deep blasts are contained in the ground and do not eject material ($\bar{d} \gtrsim 8 \times 10^{-3} \text{ m J}^{-1/3}$). The host material’s weight and strength are large enough to “contain” the blasts. Energy is dissipated by friction and anelastic alteration, or transported elastically as seismic waves. At intermediate scaled depths ($\bar{d} \simeq 4 \times 10^{-3} \text{ m J}^{-1/3}$), material is excavated efficiently, which results in the largest craters. Shallow blasts ($\bar{d} < 4 \times 10^{-3} \text{ m J}^{-1/3}$) create a smaller crater. Larger parts of E_b couple with the atmosphere and fewer with the

105 host, resulting in a large atmospheric pressure pulse. These regimes are backed up by
 106 extensive studies from military and mining research (Holsapple & Schmidt, 1980; Lee
 107 & Mazzola, 1989; Ehrgott et al., 2011; Dillon, 1972; Qiu et al., 2018), as well as research
 108 motivated by volcanology (Ambrosini et al., 2002; Sato & Taniguchi, 1997; Goto et al.,
 109 2001; Valentine et al., 2012; Sonder et al., 2015; Ross et al., 2013). Two lengths which
 110 scale with the 1/3 power of E_b and which differ by a factor 2, for example two crater radii
 111 created by two single subsurface blasts, were caused by blast energies which differed by
 112 a factor $2^3 = 8$.

113 Similar phenomenological regimes exist for a blast wave propagating in air. The
 114 distance from explosion source, r , may be scaled by blast energy and air density ρ

$$\bar{r} = \frac{\rho r}{\rho_0 E_b^{1/3}} \quad . \quad (2)$$

115 The reference density ρ_0 is a value known from a case for which the scaled distance is
 116 known. Similar to \bar{d} , \bar{r} may be used to categorize an observation distance into far ($\bar{r} \gtrsim$
 117 $6 \times 10^{-2} \text{ m J}^{-1/3}$), in which the peak pressure drops with \bar{r}^{-1} , intermediate ($\bar{r} \simeq 6 \times 10^{-3} \text{ m J}^{-1/3}$),
 118 or near ($\bar{r} \lesssim 10^{-3} \text{ m J}^{-1/3}$), (Kinney and Graham (1985)).

119 Less studied, from a volcanological perspective, is the effects of scaled depth on mon-
 120 itoring signals such as seismic, acoustic, and infrasound, particularly in cases involving
 121 multiple explosions occurring in rapid succession. Crater structures and ejecta products
 122 of such blasts are analyzed, and allow to connect their geometries and stratigraphy to
 123 energy, explosion locations and sequencing. These field findings also reveal the complex-
 124 ities of the natural processes, which limit the straight forward application of simple ex-
 125 plosion models (Taddeucci et al., 2010). Some factors controlling the dynamic behav-
 126 ior and energy scaling have a common base with other applications of explosives in the
 127 fields of military or mining research (Ambrosini & Luccioni, 2006; Qiu et al., 2018). Such
 128 applications allow the scaling of lengths with a blast’s energy, and use the depth below
 129 the surface to quantify its confinement. The scaling relationships were found experimen-
 130 tally, and while in detail the phenomena associated with a subsurface explosion depends
 131 on factors such as host material strength, rough phenomenological regimes can be iden-
 132 tified that are primarily related to energy and depth combinations. Energy scaling was
 133 experimentally verified across length scales ranging from 10^{-2} m to 10^3 m , and energies
 134 from 10^3 J to 10^{15} J (Strange et al., 1960; Vortman, 1968; Sato & Taniguchi, 1997). En-
 135 ergies of most volcanic eruptions fall into this range (Valentine et al., 2014), motivating
 136 either direct applicability of the methods or a version adapted to volcanic activity.

137 Here we report results of experiments that focus on the effects of multiple explo-
 138 sions, closely spaced and timed, on ejecta, crater morphology, and geophysical signals.
 139 Such explosions show different behavior depending on the state of topography and host
 140 conditions at time of explosion. Both are varying rapidly, which causes ejecta jets to be-
 141 come asymmetric (Figure 1, supporting video S1–S4), and can be observed on volcanic
 142 scale (Voight, 1981). A volcanic explosive source was replaced by time- and energy-constrained
 143 chemical explosions. Previous experimental studies showed that this approach has im-
 144 portant implications for field-scale analysis and interpretation (Sato & Taniguchi, 1997;
 145 Goto et al., 2001; Graettinger et al., 2014; Bowman et al., 2014; Valentine et al., 2014,
 146 2015; Sonder et al., 2015; Graettinger et al., 2015; Macorps et al., 2016; Graettinger, Valen-
 147 tine, & Sonder, 2015). In these previous experiments explosive charges were detonated
 148 separately, and the effects of each single detonation on the surface morphology and ejected
 149 material were studied before detonating the next charge. While the approach is relevant
 150 to many volcanic settings, observation shows that during explosive eruptions many ex-
 151 plosions can occur closely spaced in time (Matoza et al., 2014; Park et al., 2021) or si-
 152 multaneously, superposing their tephra jets, to create one single cumulative eruption col-
 153 umn (Dürig, Gudmundsson, & Dellino, 2015). Our study tests whether the results of pre-

For each of the experiments reported here six charges were buried and detonated in test pads which were filled with unconsolidated granular material. The setup roughly follows previous studies on craters, each of which was created by more than one explosion (“multiblast craters”) in which charges were detonated, and their blasts studied one at a time (Valentine et al., 2012; Graettinger et al., 2014; Sonder et al., 2015). The explosive material was Pentex™, which is a proprietary compound material with major components including trinitrotoluene (TNT) and pentaerythritol (PETN). It has a specific energy of $4.85 \times 10^6 \text{ J kg}^{-1}$; each charge had a mass of 90 g which corresponds to an energy of $4.37 \times 10^5 \text{ J}$. The six charges were detonated in a timed sequence of 0.5 s between each detonation. Accuracy of detonation timing was better than 10^{-3} s . This timing was selected to ensure that the ejecta jet of each blast interacted with that of the preceding blast. Two plan-view configurations were set up; one with three charge epicenters in a line; another with three epicenters corresponding to the apexes of a triangle. Charges were arranged vertically on top of one another, at two depths, 30 cm and 60 cm (Figure 2). At the given blast energy 30 cm corresponds to a scaled explosion depth of $3.95 \times 10^{-3} \text{ m J}^{-1/3}$, a value very close to optimum excavation conditions. Horizontal spacing was chosen, such that the horizontal neighbor charge location would be within the footprint of a single blast at optimum depth, but close to its border. At pads 1 and 3 the upper charges were detonated in sequence, followed by the three lower charges. At pads 2 and 4, charges beneath each epicenter were detonated in a sequence of shallow-first and deeper-second (Figure 3).

209

210

211

The blast sequences were monitored by high-speed and normal speed video cameras. A set of six cameras was arranged in a hemicycle, at a distance between 20–30 m to accurately capture directions of ejected materials. Drone-based video was recorded

Figure 2: (Caption on next page)

187 **Figure 2:** Multi-sensor stations were placed in a radial line every 50 m starting at 30 m
 188 distance from the test pads. Each station included compact broadband seismic and in-
 189 frasonic sensors as well as broadband (“acoustic”) microphones. Acoustic microphones
 190 were placed in a 30 m radius semicircle around the center of the test pads. Another set
 191 of microphones was placed in a radial line from the test pads ranging from 30 m to 80 m
 192 distance. 12 geophones were placed every 2.5 m starting at 12 m distance from the pads
 193 center, and 11 more along the same direction every 5 m following that. The last geophone
 194 had a distance of 99.5 m from the pads center. Six identical cameras recorded the experi-
 195 ments also in an arc of about 30 m distance. Other cameras recorded from a 50 m distance
 196 location.

198

199

200 **Figure 3:** Firing sequence of the four test pads. Numbers indicate the position of the
 201 firing sequence. Charges were fired in one after another in 0.5 s intervals. For any number
 202 i between 1 and 6 the corresponding charge was fired $(i - 1) \cdot 0.5$ s after the first charge.
 203 In pads 1 and 3 the upper charges (buried at 30 cm depth) were the first three to be fired,
 204 before the lower level (buried at 60 cm depth) was fired in the same lateral sequence as
 205 the upper ones. In pads 2 and 4 charge pairs located at same horizontal location were
 206 fired consecutively (upper level 0.5 s before lower level).

208

212 to determine lateral jet directions and material motion. High-speed cameras recorded
 213 at 300, 500 and 5000 fps.

214 Seismo-acoustic records were made using a combination of seismometers, geophones,
 215 infrasound-microphones (“infrasound sensors”) and higher frequency broadband micro-
 216 phones (“acoustic microphones”). The deployed seismometers and infrasound sensors fit
 217 into the SEED broadband category (band code “C”, Ahern & Dost, 2012). Seismome-
 218 ters and infrasound sensors were recorded at 400 Hz or 500 Hz. Deployed infrasound sen-
 219 sors had a flat frequency response between 3×10^{-2} Hz and Nyquist frequency. Two types
 220 of the acoustic microphones were used, with linear (± 2 dB) response from 3.15 Hz to 20 kHz
 221 and 4 Hz to 80 kHz (Table 1). Despite the short hand “acoustic microphones” these sen-
 222 sors range far into the ultrasonic range. Recordings in this frequency range are very rare

223 for volcano seismo-acoustics or not available at all. High-frequency recordings typically
 224 end around 10 kHz (Taddeucci et al., 2021).

225 From these sensors seismo-acoustic measurement stations were assembled for specific
 226 purposes. Station type (a) was dedicated to measure the radial decay of airborne-
 227 and ground based blast signals. For each of the type (a) stations a 3-component seismome-
 228 ter, an infrasound microphone and two acoustic microphones were used. The seismome-
 229 ter was placed 1 m below-, the infrasound sensor just below the surface. The microphones
 230 were mounted 4 m above ground, pointing towards the blast source, and just above ground,
 231 pointing downwards. Seven type (a) stations were placed every 50 m in a radial line, start-
 232 ing at 30 m distance from the test pads center, so that the last station was at 380 m dis-
 233 tance (Figure 2). Station type (b) was dedicated to the depth dependency of blast sig-
 234 nals. One station was assembled which consisted of three 3-component seismometers, placed
 235 132 cm, 75 cm and 18 cm below the surface, and one infrasound sensor, placed just be-
 236 low the surface. Station (b) had a distance of 30 m from the blast pads center (Figure 2).
 237 Station type (c) was dedicated to measure the angular dependency of the airborne sig-
 238 nals. For each of them two acoustic microphones were placed 2.44 m and 1.22 m above
 239 ground. Type (c) stations were placed in a 30 m radius semi-circle around the center of
 240 the blast pads. Angles range from 0° to 180° and were arranged so that the 90° station
 241 was also the start of the type (a) radial line (Figure 2). Seismo-acoustic setup also in-
 242 cluded a line of 23 geophones to record ground speeds at 12 m–100 m distance along the
 243 type (a) radial line.

244 Ejected material was collected in two box arrays, separated at an angle $> 45^\circ$ to
 245 collect material from 2.5–13.5 m from the charge assembly’s center. The sample arrays
 246 were re-positioned for each experiment, so that they were always centered around an ex-
 247 plosion site. One array was typically at an angle $\phi = 90^\circ$. The other array had differ-
 248 ent orientations for each pad, because other equipment and arrangements restricted the
 249 available space (Figure 5).

250 After the charges had detonated and ejecta jets had dissipated, photographs of the
 251 produced compound craters were taken for photogrammetry (structure from motion) anal-
 252 ysis. Photographs were taken using (a) the same UAVs that also recorded blast videos,
 253 and (b) using a standard SLR camera, operated by a (ground-based) person. A subset
 254 of the photographs was the base for digital elevation models (DEMs) that were created
 255 using the commercial photogrammetry software Metashape™, generally following pre-
 256 vious experiments (Graettinger, Valentine, & Sonder, 2015). The resulting DEMs have
 257 a spatial resolution between 1 cm and 1.5 cm for pads 1–3, and 2.5 cm for pad 4. All crater
 258 profiles- and sizes presented below are based on these elevation models.

Table 1: Sensor setup of the three seismo-acoustic station types.

Station Type Dependency Deployment	Sensors Per Station ¹	Vertical Setting (Direction) ²	Sampling Rate	Frequency Range (± 2 dB) ³	Remarks
type (a) <i>radial</i> 7 stations	seismometer	−1 m	400 Hz		Nanometrics 120s Trillium Compact Posthole
	infrasound	0 m			
	microphone 1	+4 m (towards blast)	204.8 kHz	3.15 Hz – 20 kHz	1/2" pre-polarized GRAS 40AE, 40AO
	microphone 2	+0.1 m (towards gnd.)			
type (b) <i>depth</i> 1 station	seismometer 1	−0.18 m	500 Hz		Guralp CMG3ESP 60sec
	seismometer 2	−0.75 m			
	seismometer 3	−1.32 m		0.03 Hz – 250 Hz	Honeywell Differen- tial Pressure Sensor
	infrasound	−0.05 m			
type (c) <i>angular</i> 6 stations	microphone 1	+2.44 m	204.8 kHz	4 Hz – 80 kHz	1/4" pre-polarized GRASS 40BE
	microphone 2	+1.22 m			

¹: Each seismometer in any of the stations had three components, North ('N' or '1'), East ('E' or '2') and vertical ('Z'). Components were aligned vertically (positive downward, 'Z'), radially (positive pointing away from the direction of the blast source, 'N', '1'→'R') and to the transverse direction (perpendicular to radial, 'E' or '2'→'T').

²: Vertical distance relative to local ground surface: positive above, negative below. Direction in parentheses is the direction of the microphone maximum sensitivity.

³: Upper limit refers either to Nyquist frequency or to sensor limit, see text. The ± 1 dB frequency range of the 40 AE, 40 AO is 5 Hz – 10 kHz; frequency range of the 40 BE is 10 Hz – 40 kHz.

259 3 Observations and Results

260 3.1 Qualitative Observations

261 For all pads, the initial blast transported the greatest mass of material. From the
 262 main observation direction this charge was located at the top-left end of the linear se-
 263 tups of pads 1 and 2, and at the top-rear corner of the triangular setups of pads 3 and 4.
 264 Size and speed of these initial blasts (jets) were comparable to previously conducted ex-
 265 periments (Valentine et al., 2012). Ejecta jets of the quieter blasts showed similar thin-
 266 ning behavior as was observed in previous experiments for blasts under pre-existing crater-
 267 topography (Ross et al., 2013; Graettinger et al., 2015). Some jets had a main direction
 268 that was not vertical, but had a certain direction towards the main (temporally chang-
 269 ing) crater void showing similarities with previously conducted off-center blast exper-
 270 iments (Valentine et al., 2015). For pads 2 and 4, for which the lower charges were fired
 271 only 0.5 s after the upper charge (at same lateral location), the perceived loudness (not
 272 measured amplitude) of these lower charges was significantly larger compared to the pre-
 273 vious optimum depth blast. In contrast, for pads 1 and 3, for which lower charges were
 274 fired 1.5 s after the upper charge at same lateral location, the blast noise was significantly
 275 muffled (Table 2).

285 3.2 Jets, Craters and Ejecta

286 Unlike past experiments in which a crater was analyzed after each individual blast,
 287 the timing of these multiblast experiments only allows for inspection of the final crater
 288 and ejecta. This crater is the cumulative product of six blasts that migrate vertically and
 289 laterally through the host. The blast sequences in pads 1 and 2 created craters elongated
 290 along the axis of the charges. The final craters of the triangular blast sequences (pads
 291 3 and 4) were more round, with some visibility of single-charge crater outlines in the tri-
 292 angle’s corners (Figure 4).

301 The deepest points of the pad 1 and pad 2 craters were located between the cen-
 302 tral and right charge positions in the x -direction, and in close proximity to the symme-
 303 try line along the charges in y -direction. The lower right charge was always the last to
 304 detonate. The crater profiles preserved a stepped floor centered over the final charge (Fig-
 305 ure 4). The ejecta showed a prominent ray (ridge of material) that extended from the
 306 final charge location out of the crater in the direction of elongation ($\varphi = 180^\circ$). Parts
 307 of the ray could be traced more than 10 m from the crater. For pad 1, one of the ejecta
 308 sample arrays was in line with this ray (supplementary video S1); in this direction the
 309 ejected mass per area was a factor $\simeq 10$ higher compared to the material collected by
 310 the array perpendicular to the charge line (Figure 5). Also, mass distribution is better
 311 described by an exponential distribution in the $\varphi = 180^\circ$ -direction compared to the 90° -
 312 direction which is better approximated by a power law. Isolated pieces of shallow-sourced
 313 gravel from pads 1 and 2 were observed further from the charges; one of them over 30 m
 314 away from pad 2, in the $\varphi = 180^\circ$ -direction.

315 The asymmetry of ejecta distribution around the linear charge array is similar to
 316 what was observed in previous off-center multiblast configurations with temporally well
 317 separated charge detonations (Valentine et al., 2015). However, in those experiments a
 318 steep ejecta ring was formed on the side of the crater opposite to the direction of jet in-
 319 clination (Graettinger, Valentine, & Sonder, 2015). This steep ejecta rim was not observed
 320 in the here presented, overlapping blast sequences.

321 The triangular blast sequences of pads 3 and 4 produced more equant crater shapes
 322 resembling blurred circles around the triangular blast centers (Figure 4). Compared to
 323 the linear setups the deepest points of the craters were located laterally closer to the cen-
 324 troid and had a larger distance to the last blast’s center. The pad 3 crater had a low point
 325 between the first and second (lateral) blast locations. Pad 4 had the low point close to

276 **Table 2:** Qualitative comparison of blast experiment configuration and resulting noise
 277 and direction. The “left” and “right” labels refer to the jet directions as seen from the
 278 main observation location. Polar- and inclination angles are also illustrated in Figure 2.

280 ¹: Delay of the lower charges, relative to the upper charge at same lateral location (cf.
 281 Figure 3).

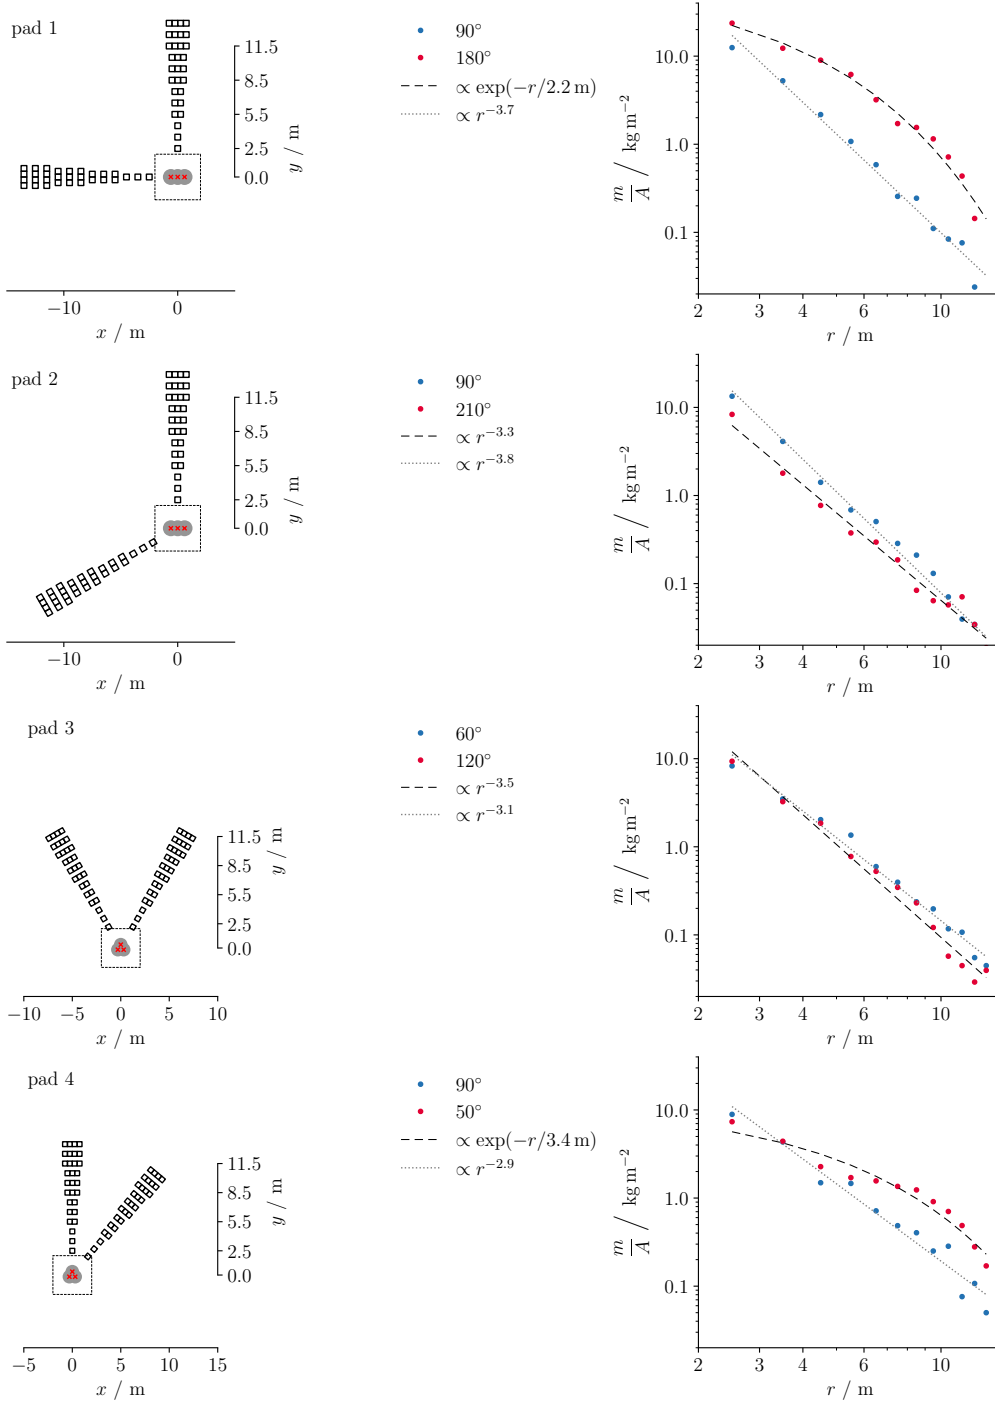

282 ²: Polar angle is counted counter clock wise, and 0° along the axis parallel to the charge
 283 lines of pads 1 and 2, pointing to the right as seen from main observation direction.

293

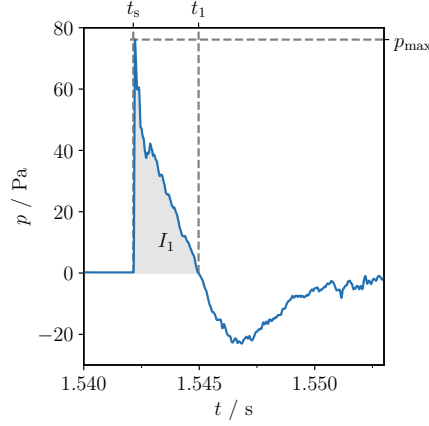

294 **Figure 4:** Map view and selected crater profiles of the crater structures. Red crosses
 295 and boxes mark the locations of explosive charges, blue circles show the deepest points of
 296 the craters. The pre-blast surface was at $z_{cs} = 0$. The linear charge arrangements (pads
 297 1 and 2) created a stepped profile that reflect the blast history to some extent. Their
 298 deepest point was about 30 cm, the upper charge depth. Sequences shot in the triangular
 299 geometries (pads 3 and 4) excavated significant amounts of material from below 30 cm.

326 its centroid. Both of the craters had shallow slopes near the crater rim, and steeper slopes
327 closer to the center. Ejecta were concentrated in three main directions for pad 3, and
328 two for pad 4. Compared to the linear charge setups, the observed ejecta concentrations
329 of the triangular sequences were less pronounced. The ejecta concentrations originate
330 from one vertex of the charge configuration to bisect the opposite side of the triangle (sup-
331 porting video S3). The pad 3 sequence had ejecta concentrations correlating to all three
332 lateral charge positions. In the pad 4 sequence ejecta rays only correlated to blasts 3, 4
333 ($\varphi \simeq 150^\circ$) and 5, 6 ($\varphi \simeq 30^\circ$), since the first two blasts occurred in an effectively radi-
334 ally symmetric setting (blast 1 under flat topography, blast 2 under an approximately
335 radially symmetric transient cavity).

336

337 **Figure 5:** Ejected mass per area at distances r from the crater center for the four blast
 338 sequences. Blue points show data of a collection branch in the $\varphi = 90^\circ$ -direction. For
 339 pad 1, the other collection branch was at $\varphi = 180^\circ$, which was the main ejection direction.
 340 This branch follows an exponential decay. The 90° -branch follows a power law in all pads.
 341 This branch shows similar decay at higher rates for the linear charge setups in pads 1
 342 and 2 (decays with power $\simeq 3.75 \pm 0.3$), and lower decays rates for the triangular charge
 343 setups in pads 3 and 4 (decays with power $\simeq 3.0 \pm 0.3$).

356

357

358

359

360

362

Figure 6: Typical waveform of a blast pulse as recorded by the acoustic microphones; here shown is blast #2 of pad 2, at 82 m distance from source (microphone channel 17). Also shown are characteristic times t_s (shock arrival), t_1 (first zero crossing), maximum pressure p_{\max} and impulse of the positive pulse part I_1 , that are formulated in Equations 5 and 6.

363

345

3.3 Seismo-acoustics

346

347

348

349

350

351

The explosion creates a pressure pulse that propagates faster than- or at the speed of sound. Close to the source the pressure jumps (rises discontinuously) from ambient (atmospheric) value to a maximum and then relaxes back before sinking below ambient pressure (Figure 6) and again relaxing back. At larger distances the propagation speed approaches the speed of sound and the pressure discontinuity relaxes to a steep, but finite slope.

352

353

354

355

The recorded data show strong air-to-ground and weak ground-to-air wave coupling. A high-frequency signal occurs in the seismic waveforms in close time correlation with the main blast pulses measured in air at the same location by infrasound and sonic range microphones (Figure 7a-d).

377

3.3.1 Radial Dependency of Airborne Blast Pulse

378

379

380

381

382

383

384

385

386

387

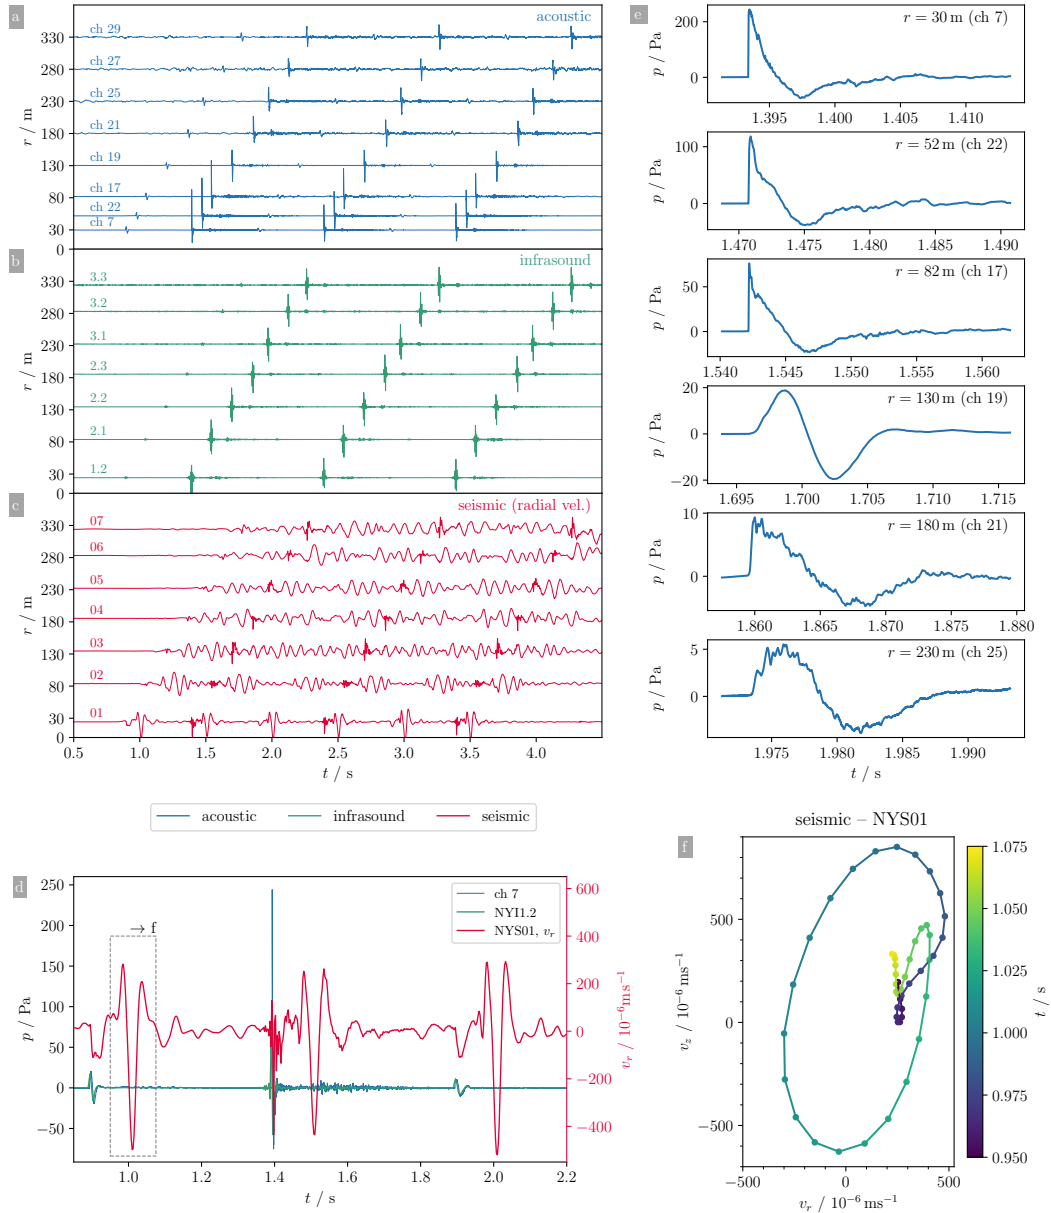

388

389

Using features of wave-forms recorded by microphones and/or seismic sensors it is possible to estimate the blast's energy, provided that scaling laws assumed in such models are valid. The scaled peak pressure and scaled impulse of a blast in air depends on the scaled distance where the pressure is measured (Kinney & Graham, 1985). This relationship can be used to determine the scaled distance of each microphone record, and with that the energy of each blast wave can be estimated. This resource will be used as a reference model, and referred to as KG85 data (or -model). For these blasts in air, the main fundamental three quantities to be scaled are distance, time, and pressure. As in the case for underground blasts distances can be scaled with blast energy E_b . Additionally, the relatively high atmospheric homogeneity allow further specification of the atmospheric density, which is often written in terms of transmission factors for scaled distance and time. Scaled distance, time, and pressure are given by

390

$$\bar{r} = \frac{f_d r}{E^{1/3}} \quad , \quad \bar{t} = \frac{f_t t}{E^{1/3}} \quad , \quad \bar{p} = \frac{p}{p_a} \quad , \quad (3)$$

364

365 **Figure 7:** Seismic- infrasound- and acoustic waveform signals of the pad 2 blast sequence.
 366 **a, b, c:** The seismic signals show high-frequency coupling at time and location of the
 367 large pressure pulses occurrence at the infrasound- and acoustic microphones. **d:** First
 368 three pulses at horizontal distance $r = 30$ m. High amplitude air-borne pressure waves,
 369 such as the acoustic (blue) and infrasound (green) signals at $t \simeq 1.6$ s correlate better with
 370 high frequency signal of the seismic channel compared to lower amplitude pulse signals at
 371 about 1.1 s and 2.2 s. **e:** Waveforms of microphone records of blast #2 show a clear transi-
 372 tion at distance < 130 m. The 130 m station recorded a more symmetric signal, while at
 373 180 m the rising slope was steeper (asymmetric) again. **f:** Particle motion of the incoming
 374 Rayleigh wave created by blast #1. The time window picked for the radial and vertical
 375 components is indicated by the dashed rectangle in d.

391 where p_a is the atmospheric pressure and the transmission factors f_d , f_t for distance and
 392 time, respectively, take the density into account in which the blast pulse propagates. They
 393 are given by

$$394 \quad f_d = \left(\frac{\rho}{\rho_0}\right)^{1/3} = \left(\frac{p_a T_0}{p_0 T}\right)^{1/3}, \quad f_t = \left(\frac{\rho}{\rho_0}\right)^{1/3} \frac{c}{c_0} = \left(\frac{p_a}{p_0}\right)^{1/3} \left(\frac{T}{T_0}\right)^{1/6}. \quad (4)$$

395 The index $_0$ refers to values of a known blast case. The model only applies to explosive
 396 shocks in air. Our recorded pressure pulses show most of the characteristic features of
 397 a free air explosion, indicating that enough energy was not contained in the ground, so
 398 that an estimate of the un-contained energy, E_a , which created a shock pulse in the at-
 399 mosphere, seems appropriate. Comparison to the known yield of the detonation charges,
 400 E_b , can then give information of the effect of explosion depth.

401 Another widely used quantity to measure a blast's intensity, damage potential and
 402 energy is its impulse per crosssectional area (Schnurr et al., 2020; Guzas & Earls, 2010;
 403 Kinney & Graham, 1985; Bush et al., 1946), which can be obtained as the time integral
 404 of the initial positive pressure peak of a microphone pressure curve as

$$405 \quad I_1 = \int_{t_s}^{t_1} p dt \quad . \quad (5)$$

406 Here t_s is the start time (time of arrival of the pulse at the sensor's location) and t_1 is
 407 the time of first zero crossing of the pressure curve (Figure 6). This time interval always
 408 contains the peak pressure. The corresponding scaled impulse is a compound of scaled
 409 pressure and time components

$$410 \quad \bar{I}_1 = \int_{\bar{t}_s}^{\bar{t}_1} \bar{p} d\bar{t} = \frac{f_t}{p_a E_b^{1/3}} I_1 \quad . \quad (6)$$

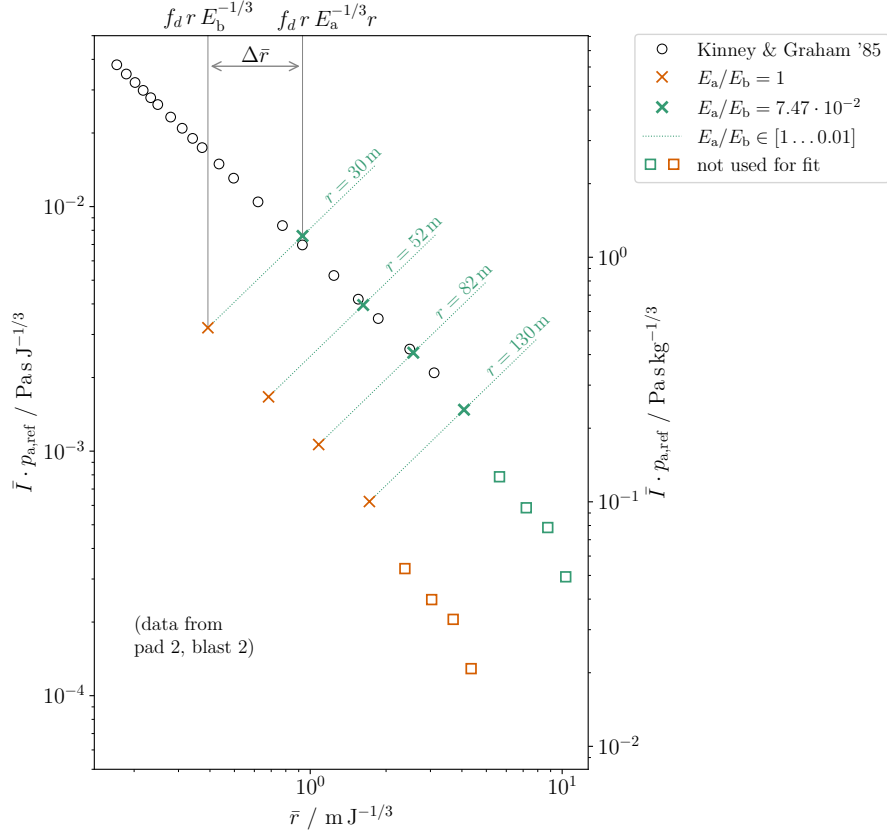

411 The KG85 data provides values up to a scaled distance of $3.1 \text{ m J}^{-1/3}$ ($500 \text{ m kg}^{-1/3}$).
 412 According to this dataset the scaled pressure and scaled impulse decay with $1/\bar{r}$ at re-
 413 latively large distances ($\bar{r} \gtrsim 10^{-2} \text{ m J}^{-1/3}$, $20 \text{ m kg}^{-1/3}$). The explicit values for the de-
 414 cay are

$$415 \quad \bar{p} = \frac{a_{p,\text{ref}}}{\bar{r}}, \quad a_{p,\text{ref}} = 5.135 \times 10^{-3} \text{ m J}^{-1/3}, \quad (7)$$

$$416 \quad \bar{I}_1 = \frac{a_{I,\text{ref}}}{\bar{r}}, \quad a_{I,\text{ref}} = 5.923 \times 10^{-8} \text{ m s J}^{-2/3}. \quad (8)$$

418 As is common in the analysis of blast waves (Garces, 2018; Kinney & Graham, 1985),
 419 peak pressures were not directly read as the maximum of the measured pressure curve,
 420 but impulse I_1 was calculated and compared to a function representing a blast pulse shape.
 421 We used a modified Friedlander shape $\bar{p}(t) = \bar{p}_p \left(1 - \frac{t-t_s}{t_1-t_s}\right) \exp\left(-\alpha \frac{t-t_s}{t_1-t_s}\right)$, see e.g. Marchetti
 422 et al. (2013). The value of p_p that fits the measured I_1 best was used for the peak over-
 423 pressure. The impulse reference data are somewhat unclear, since the given interpola-
 424 tion function (Appendix B) deviates from the given data points by 17%. The propor-
 425 tionality constant $a_{I,\text{ref}}$ in Equation 8 is a modified value that takes this into account
 426 and is a better fit to the provided reference data.

427 The more contained blasts did not create large enough blast pulses to make a rea-
 428 sonable comparison with the KG85 reference data. However, all initial and the perceived
 429 louder blasts of pads 2 and 4 (blasts 2, 4, 6) created wave forms that were consistent with
 430 blast pulses and could be compared. In those cases peak pressure data were in agree-
 431 ment with a $1/r$ dependency at distances of up to 100 m. The impulse data stay con-
 432 sistent up to about 130 m distance (Figure 9a and b). At larger distances the values de-
 433 viate significantly from $1/r$.

438

Figure 8: Effect of blast confinement illustrated by a scaled impulse vs. scaled distance plot. Straight forward calculation of scaled distance using the blast's total energy E_b puts the measured scaled impulse (red markers) below the reference values (black circles). The fitting procedure moves the measured values along the green lines. Since both, impulse and distance scale with $E^{-1/3}$ their scaled values increase if E decreases. Green markers show values for minimum deviation from reference which correspond to energy E_a .

446

To compare the measured impulse values to the scaled reference, an r^{-1} dependency was fitted to the un-scaled values of a given blast pulse, and the fitting constant a_I was used to determine the location in the scaled graph. This determines an energy, E_a ("atmospheric energy"), that creates the pressure pulse:

 434
 435
 436
 437

$$\begin{aligned}
 \bar{I} &= \frac{a_{I,\text{ref}}}{\bar{r}} = \frac{a_{I,\text{ref}} E_a^{1/3}}{f_d r} \\
 &= \frac{f_t}{p_a E_a^{1/3}} I = \frac{f_t}{p_a E_a^{1/3}} \frac{a_I}{r}
 \end{aligned} \tag{9}$$

$$E_a = \left(\frac{f_d f_t}{p_a} \frac{a_I}{a_{I,\text{ref}}} \right)^{3/2} \tag{10}$$

Since both, distance and impulse scale with $E_a^{1/3}$, the procedure 'moves' values on either axis when changing energy (Figure 8). The result are scaled distances at the end of the KG85 reference scale ($\bar{r} \gtrsim 0.6 \text{ m J}^{-1/3}$, $100 \text{ m kg}^{-1/3}$). From the scaled distance \bar{r} a real distance r corresponds to the energy $E_a = (r/\bar{r})^3$, which can be interpreted as the

 447
 448
 449
 450

451 energy not contained in the ground, and is smaller compared to the blast energy E_b . E_a
 452 was found to be around 1.5% of E_b for the initial blasts, and about 5–7.5% of E_b for the
 453 loud blasts in pads 2 and 4 (Figure 9c and d, Table 3).

454 Ford et al. (2014) determined distance- and depth dependent energy partitioning
 455 of explosions above and below ground using a model for the airborne signal that, after
 456 some re-formulation (Appendix C), can be written as

$$\bar{I}_1 = \frac{b_1}{\bar{r}} \frac{e^{-\bar{d}/\bar{d}_3}}{(1 + e^{-10\bar{d}/\bar{d}_3})^{1/10}} \quad (11)$$

457 Here $b_1 = 1.15 \times 10^{-7} \text{ s m J}^{-2/3}$ and $\bar{d}_3 = 1.2 \times 10^{-3} \text{ m J}^{-1/3}$. Evaluated at $\bar{d} = 0$
 458 this model expects a ca. 7% smaller scaled impulse (factor $2^{-1/10}$, $\simeq 0.93$) at a given
 459 distance compared to a free air blast. A larger discrepancy exists with respect to the KG85
 460 data: The two constants for the \bar{r}^{-1} dependency, $a_{I,\text{ref}}$, b_1 differ by a factor 0.51. Eval-
 461 uating equation 10 using b_1 instead of $a_{I,\text{ref}}$ yields a factor $(a_{I,\text{ref}}/b_1)^{3/2} \simeq 0.37$ reduced
 462 values for E_a . The dataset presented here does not contain a zero depth or free air blast,
 463 and therefore cannot decide for one of the models. Energy values listed in Table 3 used
 464 the KG85 constant, and should be adjusted if used in connection with Equation 11.

486 *3.3.2 Blast Energy, Charge Depth and Explosion Sequence*

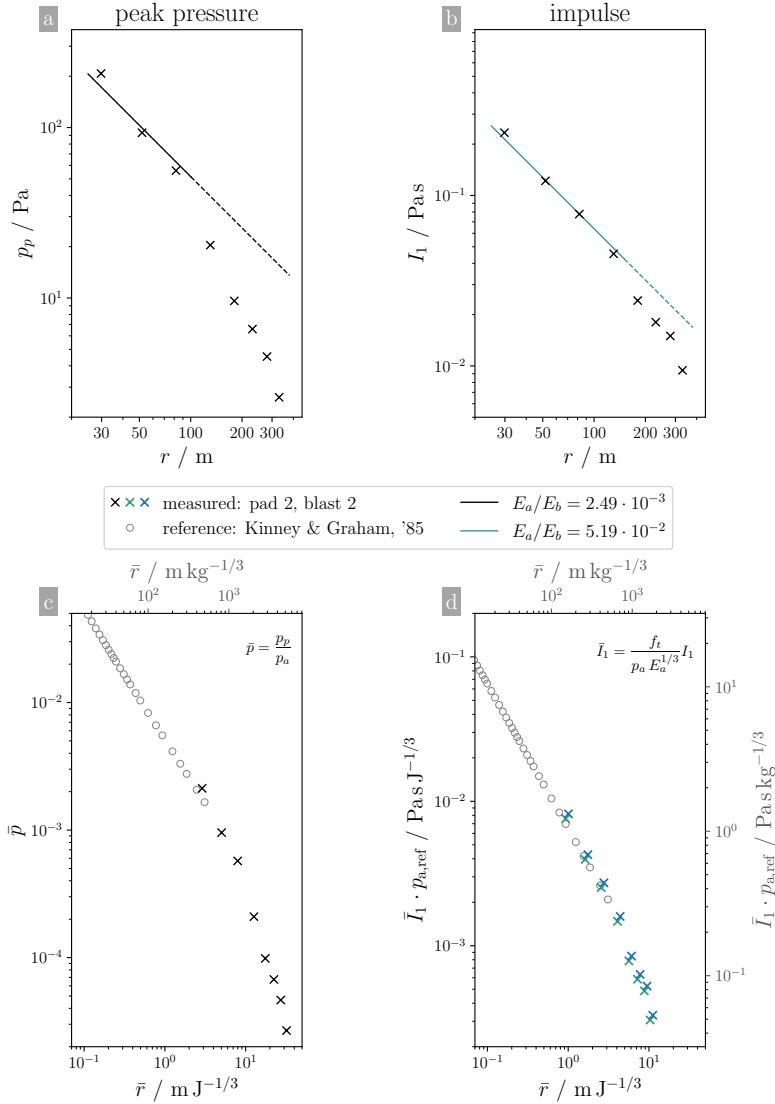

487 Equation 11 and microphone records of previous blast sessions, carried out in very
 488 similar host materials and with similar explosives, show that scaled impulse decays rapidly
 489 with scaled depth (Appendix A). A somewhat more accurate match with experimental
 490 data is obtained for the peak pressure dependency on depth. Therefore the following is
 491 formulated using a peak pressure dependency. At depths $\bar{d} < 5 \times 10^{-3} \text{ m J}^{-1/3}$ peak pres-
 492 sure can be approximated by a product of an exponential which contains the depth part
 493 and an amplitude containing the radial dependency:

$$494 \quad p_p = A(\bar{r}) e^{-\bar{d}/\bar{d}_0} \quad (12)$$

495 Here the scaled depth related constant $\bar{d}_0 = 5.4 \times 10^{-4} \text{ m J}^{-1/3}$. This approximation is
 496 valid for scaled depths smaller than $5 \times 10^{-3} \text{ m J}^{-1/3}$ (Figure A1).

497 The first charge of a blast sequence detonated under a flat surface in unaltered host
 498 material. The following charges detonated under changed topography and somewhat al-
 499 tered host material, since their lateral spacing (0.6 m , $8 \times 10^{-3} \text{ m J}^{-1/3}$) corresponds ap-
 500 proximately to the maximum crater radius for that blast energy, and similarly, the ver-
 501 tical spacing (0.3 m , $4 \times 10^{-3} \text{ m J}^{-1/3}$) had, approximately, the optimum depth. Previ-
 502 ous experiments showed that for such scaled distances the blast’s jet changes shape and,
 503 if the topography above the charge has an overall orientation, it will also change direc-
 504 tion (Valentine et al., 2015; Ross et al., 2013). If the pre-blast topography is known, parts
 505 of the altered surface morphology can be accounted for by the use of an effective scaled
 506 depth (Sonder et al., 2015). In case of 0.5 s blasting delays the topography is however
 507 not known. However, the Sonder et al. (2015) analysis also shows that an effective ex-
 508 plosion depth rarely deviates by more than 10–20% from the distance to the closest point
 509 to the surface, which is typically the crater bottom. With this approximation, i.e. ne-
 510 glecting the crater shape but not its depth, it is possible to evaluate Equation 12 for peak
 511 pressures of blasts that were shot at same lateral location for the two different blast de-
 512 lays, 0.5 s and 1.5 s that were realized.

513 For the pad 1 and 3 experiments this applies to the following pairs of blasts: (1, 4),
 514 (2, 5), and (3, 6). For the pad 2 and 4 experiments the blast pairs with same lateral lo-
 515 cation are (1, 2), (3, 4) and (5, 6). Evaluating Equation 12 for two peak pressures at same
 516 scaled distance leaves only the scaled depth to change. For example, considering the ra-

465

466 **Figure 9:** Comparison of peak pressure p_p and impulse I_1 with respect to their appli-
 467 cability to estimate an explosion energy, and their compatibility to the scaled air blast
 468 data by Kinney & Graham, 1985 (KG85). **a, b:** The impulse data show a better agree-
 469 ment with the r^{-1} -trend. Energies E_a estimated from peak pressures are about a factor
 470 10 smaller compared to the impulse-based estimates. The p_p -values start to deviate sig-
 471 nificantly from the r^{-1} -trend at distances $r > 100$ m. The impulse values start deviating
 472 for distances $r > 150$ m. **c:** Only the largest blasts produced scaled peak pressures that
 473 are comparable to the KG85 values. **d:** Scaled impulse values show a larger overlap with
 474 KG85. This is partially caused by the larger energy estimates, which reduce the scaled
 475 impulse *and* the scaled radius.

477 **Table 3:** Results of the acoustic signal analysis: Acoustic energy, E_a , its part of total
 478 blast energy, and reduced depths for all experiments. Only signals from the radial mi-
 479 crophone line were used. All E_a values were derived from a fit to the impulse-distance
 480 relationship (Equations 6 and 8). Only I_1 -values that followed an r^{-1} -dependency were
 481 used for the fit (Figure 9). For the loud blasts of pads 2 and 4 (blasts 2, 4, 6) the r^{-1}
 482 dependency ended for $r > 130$ m. which was the case for microphones at distances up to
 483 130 m ($\bar{r} \leq 1.71 \text{ m J}^{-1/3}$, $276 \text{ m kg}^{-1/3}$).

Pad	Blast	mics used ¹	Distance range ² (m)	E_a $\times 10^3 \text{ J}$	E_a/E_b %	d_{red}	\bar{d}_{red} $\times 10^{-3} \text{ m J}^{-1/3}$

485

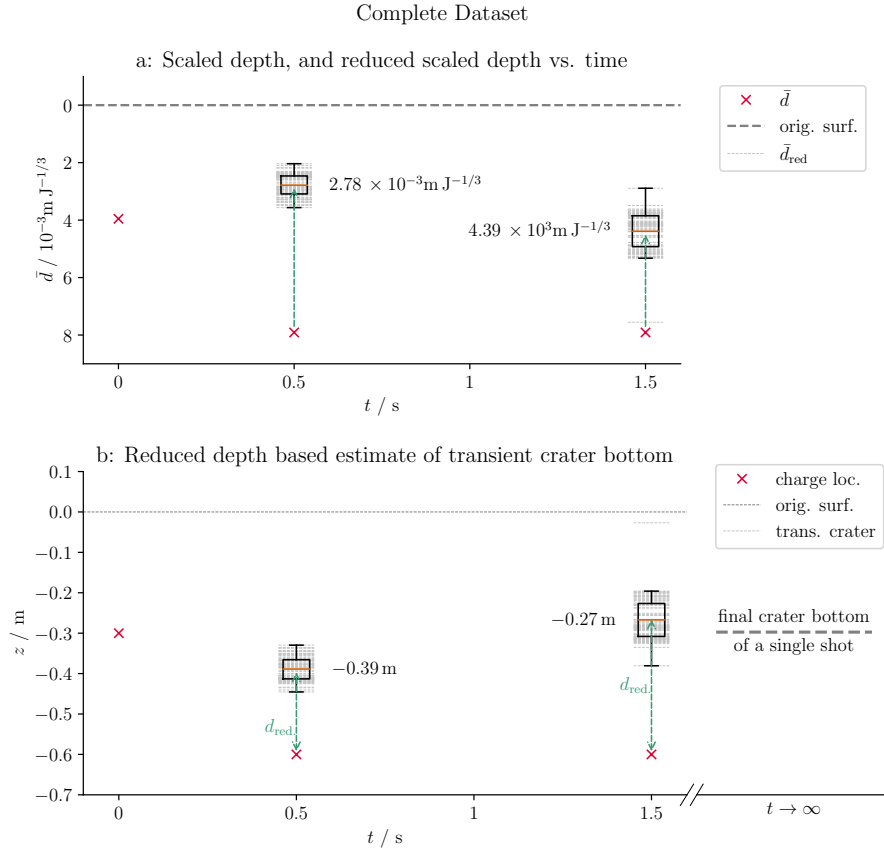

¹: Number of microphones used to fit the radial dependency to the data.

²: Minimum and maximum distance of the microphones used to determine E_a .

517 tio of peak pressures of pad 2's blasts 2 and 1 relates the scaled depth of blast 2 to the
 518 previous one by

$$519 \quad \bar{d}_{2,r} = \bar{d}_1 - \bar{d}_0 \ln \frac{p_{p,2}}{p_{p,1}} \quad . \quad (13)$$

520 This formula can be applied to any of the above listed blast couples with consistent re-
 521 sults (Figure 10a), showing that the so-derived depths are reduced by a factor 1.5–3, com-
 522 pared to their initial charge location relative to the surface. Since E_b was the same for
 523 all blasts, the lower charge at the moment of its detonation can be estimated to be at
 524 a depth $d_r = \bar{d}_r E_b^{1/3}$ below the crater bottom at that time. And because the location of
 525 the lower charge is known to be 0.6 m below the original surface, the crater bottom can
 526 be estimated at $z_{\text{bottom}} = -0.6 \text{ m} + d_r$ (Figure 10b). The two delay times show that 0.5 s
 527 after detonation the crater bottom is deeper than at 1.5 s. At 1.5 s the crater bottom is
 528 about the same location that would be expected from a blast of energy E_b at optimum
 529 depth.

530

531 **Figure 10:** Scaled charge depths (blue crosses), reduced scaled depths (gray, dashed
 532 lines: values of a single microphone, orange: average of all microphones) of all microphone
 533 sensors at one angle, plotted against time after detonation of the previous charge located
 534 vertically above. a: At 0.5 s delay, scaled depth is reduced by a factor 2–3 compared to
 535 original charge location. At 1.5 s delay scaled depth is only reduced by a factor 1.5–2. (b)
 536 Estimated of the time dependent crater bottom evolution. For comparison the dashed
 537 gray line shows the measured depth of a single shot of same charge type and energy.

Pad	Measured Footprint		Reduced Footprint		Max. Footprint	
	Area m ²	Radius m	Area m ²	Radius m	Area m ²	Radius m

Table 4: Measured-, reduced- and maximum expected crater sizes for the tested explosion configurations. The reduced footprint is the maximum possible footprint when blasting at the reduced depth. The maximum footprint is the overall maximum that can be expected from the given blast energy.

3.3.3 Seismic Signal

We present here an initial estimate of seismic energy involved in the explosion experiments. A deep analysis of the seismic records will be part of future studies. The energy radiated from a radially symmetric seismic source may be estimated from the measured square velocity of the ground (particle) motion u_r (e.g. Boatwright, 1980; Johnson & Aster, 2005)

$$E_s = 2\pi r^2 \frac{\rho_g c_g}{A} \int_0^{\infty} S u_r^2(r, t) dt \quad . \quad (14)$$

Here A and S are coefficients for signal attenuation and site response, respectively. ρ_g is the ground density and c_g the propagation speed of the ground, both at the observation location. For this first broad look at seismic energy these parameters are assumed to be constant. In this assumed energy estimate only one component of ground motion, radial component u_r is non-zero. Other seismic components are therefore ignored in the following. Then E_s can be approximated as

$$E_s \simeq F r^2 \int_0^{\infty} u_r^2(r, t) dt \quad , \quad F = 2\pi \rho_g c_g \frac{S}{A} \quad . \quad (15)$$

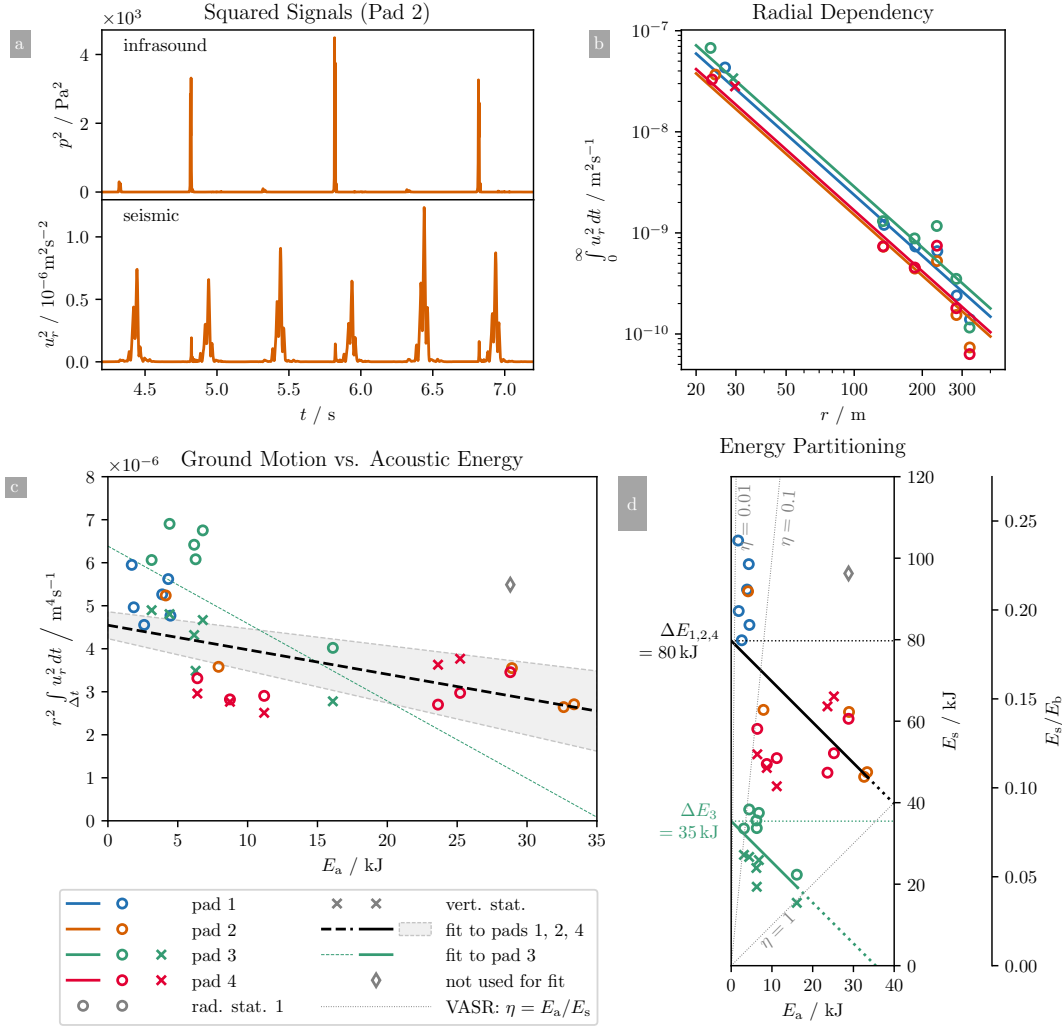

In this approximation the proportionality factor F depends on a combination of ground properties and attenuation characteristics, but not on E_s .

The multi-blast setting adds the difficulty that seismic signals originating from different blasts overlap at larger distances (e.g. for $r \gtrsim 80$ m, Figure 7c). From such distances only the cumulative seismic energy of a blast set can be determined:

$$\sum_{i=0}^{N_b} E_{s,i} = F r^2 \int_0^{\infty} u_r^2(r, t) dt \quad (\text{here } N_b = 6). \quad (16)$$

At closer ranges the blasts can be identified clearly in the u^2 signal. There u^2 decays quickly before the next pulse arrives, and integration over a finite time interval is a valid approximation for each blast (Figure 11a):

$$E_{s,i} = F r^2 \int_{\Delta t_i} u_r^2(r, t) dt \quad (17)$$

566

567 **Figure 11:** Estimate of seismic energy from squared particle velocity. **a:** Pad 2 test
 568 squared pressure signal of the infrasound sensor and squared particle velocity at first ra-
 569 dial station (30 m distance). The seismic signal shows clearly identifiable pulses that can
 570 be separated into six time intervals. As described earlier for pad 2 the airborne pressure
 571 pulses of blasts 1, 3 and 5 are much weaker as those of blasts 2, 4 and 6. In contrast peak
 572 values of u^2 are higher for blasts 1, 3 and 5, and somewhat weaker for blasts 2, 4 and 6.
 573 The trend is not as strong for the seismic signal as it is for the airborne signal. **b:** Radial
 574 dependency of squared particle velocity integral. Measured values and fitted r^{-2} curves of
 575 Equation 20 are shown. Pads 1 and 3, with sequential shot depth configuration, produced
 576 a higher squared particle velocity integral, compared to pads 2 and 4 (interchanging shot
 577 depth). To a lesser degree, the triangular pads 3, and 4 had larger values when compared
 578 to the same shot depth configuration of the linear geometrical setups of pads 1, and 2.
 579 **c:** Squared particle velocity integral dependency on E_a . Despite some scatter, data from
 580 pads 1, 2 and 4 follow a common trend, while pad 3 data has a larger slope and offset.

582

[Caption continues]

583 **Figure 11:** [*Continued*] The black dashed line is a fit of Equation 19 to data of pads 1,
 584 2, and 4. The green dotted line to the pad 3 data. Cross markers show data from ra-
 585 dial station#1, circles data from the vertical station. **d:** Seismic energy plotted against
 586 acoustic energy for all pads. Black and green lines show the anticipated (linear) relation-
 587 ships using the derived values for F and ΔE . The second vertical axis shows E_s relative
 588 to total blast energy E_b . The elastic part is ca. 17% of E_b for pads 1, 2, 4 and ca. 10%
 589 for pad 3. Gray dotted lines show the volcanic acoustic seismic ratio $\eta = E_a/E_s$ (VASR,
 590 Johnson & Aster, 2005). The blasts had VASR values between 10^{-2} and 1.

593 When compared to the airborne signals, the seismic records show an inverted trend:
 594 The ‘‘muffled’’ blasts 1, 3 and 5 of pads 2 and 4, which had a much lower airborne sig-
 595 nal created a larger seismic signal, when compared to blasts 2, 4 and 6 (Figure reffig:seisa).
 596 This behavior serves as motivation for a potential energy partitioning scheme. For a given
 597 pad configuration the assumption is made that seismic and acoustic energy of a blast add
 598 up to a constant value.

$$E_b = E_a + E_s + E_{\text{rem}} \quad (18)$$

599 In this picture a change in E_a of δE , for example by a change of blast depth, would re-
 600 sult in a change of E_s by $-\delta E$. The remaining energy E_{rem} stays constant. This energy
 601 conservation applies to each blast and to the cumulative case, which allow determina-
 602 tion of the two unknowns F and E_{rem} . With $\Delta E = E_b - E_{\text{rem}}$ the per-blast case be-
 603 comes

$$r^2 \int_{\Delta t_i} u_r^2(r, t) dt = \frac{E_{s,i}}{F} = \frac{\Delta E - E_{a,i}}{F} \quad , \quad (19)$$

604 and the cumulative case is

$$\begin{aligned} \int_0^\infty u_r^2(r, t) dt &= \frac{N_b E_b - N_b E_{\text{rem}} - \sum E_{a,i}}{F r^2} \\ &= N_b \frac{\Delta E - \langle E_a \rangle}{F r^2} \quad , \end{aligned} \quad (20)$$

605 where $\langle E_a \rangle = \sum E_{a,i}/N_b$. The difference between the two cases is that for Equation 20
 606 r is treated as independent variable, while in Equation 19 E_a is independent. The av-
 607 erage value $\langle E_a \rangle$ is a constant.

608 The left hand side values of Equation 20 were fitted to an r^{-2} dependency. The
 609 result shows the expected behavior: Pads 2 and 4 with the large airborne signals have
 610 smaller seismic signals when compared to their respective geometric counterparts pads 1
 611 and 3 (Figure 11b). The per-blast data for the right-hand side of Equation 19 show a
 612 different trend of the pad 3 data compared to the other pads (Figure 11c). For small E_a
 613 they are larger than the other pads, and then fall off quicker with rising E_a . Since for
 614 the other pads no unique trend could be determined, pad 3 was treated separately, form
 615 pads 1, 2 and 4. For both cases intercept and slope were determined. Together with the
 616 cumulative case fit, values for ΔE and F were calculated. For pads 1, 2 and 4, ΔE about
 617 17% of E_b ($\simeq 73$ kJ), for pad 3 this value is about 10% ($\simeq 45$ kJ). Highest values of E_s
 618 are a factor two larger than highest values of E_a . Consequentially in cases of observed
 619 higher E_a blasts, seismic and airborne energies were comparable (Figure 11d). To be com-
 620 plete, values for F are 3.5×10^9 J s m $^{-4}$ for pads 1, 2, 4, and 1.6×10^9 J s m $^{-4}$ for pad 3.

4 Discussion

Any number of subsurface explosions at given lateral location create crater structures (“multiblast craters”) of a limited size, determined by the explosion’s energy, because any single explosion can eject material only to a finite distance (Sonder et al., 2015). Accordingly, the sizes of the presented craters are larger than one-blast craters, but smaller than they could become when blasting many times at these lateral locations with the same energy. Overlapping footprints from laterally shifting, time separated explosions create compound craters with a footprint area that can be calculated from overlapping circles centered around blast locations (Valentine et al., 2015). For a given explosion depth a radius is related to explosion energy by the scaled radius, and therefore the footprint area is, too. The maximum crater radius that can be realized with many explosions of a given energy is related to the crater radius of one explosion by

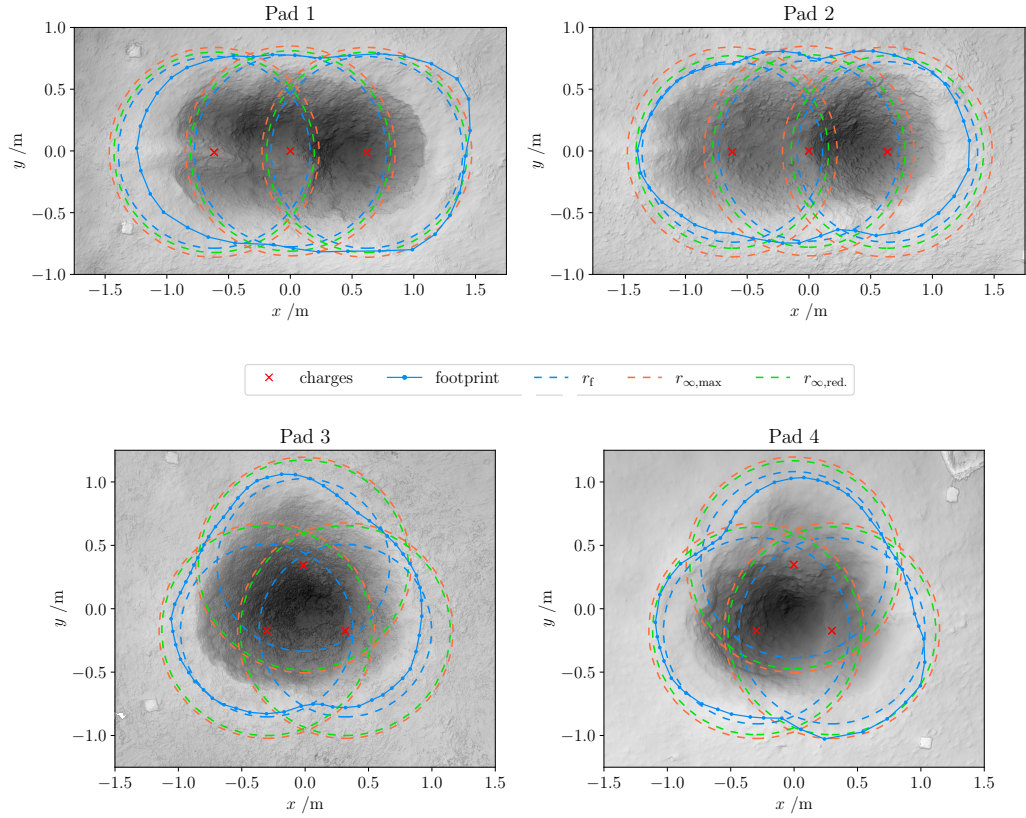

$$r_{\infty, \max} = \frac{r_{1, \max}}{1 - e^{-1/n_0}} \simeq 1.49 \bar{r}_{1, \max} E_b^{1/3} = 0.85 \text{ m} \quad , \quad (21)$$

where $n_0 = 0.9$ is an experimentally determined constant, and $\bar{r}_{1, \max} = 7.5 \times 10^{-3} \text{ m J}^{-1/3}$ is the maximum scaled radius of one explosion, which occurs at the optimum scaled depth (Sonder et al., 2015). The footprint radii measure in this study fit into this picture: they range between 0.68 m and 0.78 m, which is larger than the single explosion radius (0.57 m) and smaller than the many-blasts limit. However, the crater sizes are not consistent with respect to the blasting sequence: in case of the linear setup, pad 1 (upper before lower charges) created a larger crater compared to pad 2 (interchanging charge depths), while in case of the triangular setup pad 4 (interchanging depths) created the larger crater when compared to pad 3 (Table 4).

Equation 21 can also be used to estimate the final crater size of a hypothetical crater that would be the result of many blasts at reduced depth. It is then necessary to replace the maximum (scaled) crater radius with the reduced radius. The latter can be calculated from the scaled depth dependency, using the scaled reduced depth value. A footprint size estimated this way is larger than the measured two-blast crater, and ca. 7% smaller compared to the maximum possible crater (Table 4, Figure 12).

Determination of the atmospheric energy E_a from airborne impulse or peak pressure is possible for scaled distances up to about $5 \text{ m J}^{-1/3}$ ($800 \text{ m kg}^{-1/3}$). At larger distances this type of analysis yields faulty values. A word of caution must be added, since the empirical models by Kinney and Graham (1985) and Ford et al. (2014) yield a factor 2 to 3 different energy estimates. A more in-depth analysis that focuses on the complete seismo-acoustic dataset of the presented experiments may help here. For example, peak pressure of a weak shock (e.g. Young et al., 2015; Muhlestein et al., 2012; Rogers, 1977) decays with a power of radius slightly larger than 1. Such a dependency may be observed in the presented data (Figure 9a). Other non-linear acoustic factors and near-field topography may also play a role (Maher et al., 2020). Nevertheless, both models evaluated here result in single digit values for the percentage of the energy ratio E_a/E_b . The relatively small amounts of explosives used, have the advantage that analysis does not have to deal with complications arising from drastically changing transmission factors (Equation 4), as in the case of large scale explosive events (e.g. Kim & Rodgers, 2016, 2017) or volcanic eruptions (Matoza et al., 2009).

The changes in the apparent (“reduced”) crater depth over time show that 0.5 s after detonation the crater is about a factor 1.5 deeper compared to 1.5 s after detonation. It is not clear whether this is the time of the transient cavity’s maximum opening or not. The depth at 1.5 s is comparable to the depth of a single blast crater. For volcanic activity the timescale on which a crater forms is important. In this period part of the overlying mass confining magma in the ground is reduced, creating an effectively reduced load, changing- or enabling non-steady state processes, such as magma-water mixing and phreatomagmatism (Büttner & Zimanowski, 1998; Lorenz, 1975) or decompression driven ac-

648

649 **Figure 12:** Map views of the four craters, their footprints, and footprint equiv-
 650 alent circles of corresponding radii. All radii correspond to an explosion energy,
 651 $E_b = 4.635 \times 10^5$ J. Blue lines represent the measured footprint (topographic high).
 652 Blue dashed circles are the equivalent radii. Green lines represent the maximum possi-
 653 ble footprint that can be expected from this blast energy. Red lines show the hypothetical
 654 footprint that would be the result of many explosions at the average reduced depth as
 655 measured in each pad.

680 tivity (Gonnermann & Manga, 2007). Assuming for a moment without proof that crater
 681 formation duration scales, analog to other blast related time and length (e.g. blast depth,
 682 crater radius), with $E_b^{1/3}$, the presented results mean that for $E_b = 0.4365$ MJ crater
 683 formation lasts on the order of 1 s, which corresponds to a scaled duration of $1.3 \times 10^{-2} \text{ s J}^{-1/3}$.
 684 An event creating a crater of about 15 m diameter would need 10^9 J (Valentine et al.,
 685 2014) if created by a single blast, and would be formed in $1.3 \times 10^{-2} \text{ s J}^{-1/3} \times 10^9 \text{ J}^{1/3} =$
 686 13 s. A 25 m diameter crater would then need 44 s to form. It is, however, likely that other
 687 factors complicate such a straight forward scaling approach.

688 Despite such scaling difficulties the experiments show that explosions which occur
 689 at depths previously thought to be contained in the subsurface (Valentine et al., 2014)
 690 have to be considered potentially hazardous, if there is a realistic probability that it could
 691 occur as a result of crater formation above. The scenario of successively crater deepen-
 692 ing, which is also of military interest (Antoun et al., 2003), cannot repeat indefinitely,
 693 since the following crater needs to move material from greater depth to the surface in
 694 a finite time window, which needs energy. More experiments are necessary to test where
 695 this limit lies, and what the exact crater formation duration is.

696 Analysis of the seismic signal reveals why the pad 3 crater is smaller compared to
 697 pad 4: Pad 3 had different attenuation- and coupling conditions leading to less energy
 698 available for seismic and acoustic pressure or momentum generation (ΔE), and more en-
 699 ergy dissipated without momentum generation. The different coupling is likely the re-
 700 sult of a variation in the pads host properties: On a subjective level, personnel prepar-
 701 ing the pad for charge placement before blasting, can confirm that pad 3 ‘felt’ somewhat
 702 different compared to the others when punching holes for charge placement into the ma-
 703 terial. Such unintentional host variability highlights the sensitivity of the crater forma-
 704 tion process to host properties (see also Macorps et al., 2016). The estimate of seismic
 705 energy and the energy partitioning analysis rely on good knowledge of E_a . The assump-
 706 tions made to estimate E_s work well for large values of E_a . At smaller E_a (more con-
 707 tained blasts) scatter becomes larger, which suggests that the underlying assumption,
 708 that energy is partitioned only between seismic and airborne signal producing effects,
 709 does not apply there. The squared velocity- and pressure signals of pads 1 and 3 empha-
 710 size this trend (Supporting Information Figure S9 and Figure 11a). In a first order esti-
 711 mate combination of the available data from the blasts in pads 1, 2 and 4 was between
 712 10% and 20% of E_b , and between 5% and 10% for the blasts of pad 3. The experiments
 713 show how explosive energy is contained by friction, strength and inertia of the surround-
 714 ing (overlying) material, and how energy translates from driving ground-bound (seismic)
 715 to airborne processes, once the overarching containment parameter, scaled depth \bar{d} , changes.

716 5 Conclusions

717 Rapidly-timed subsurface blasts, occur in fields such as mining, geotechnical, mili-
 718 tary and medical applications (Qiu et al., 2018; Arora et al., 2017; Zhou et al., 2016; Mam-
 719 madova et al., 2017). Our analysis of the ejecta, crater morphology, and seismo-acoustic
 720 signals should be applicable to those situations. We highlight volcanic eruptions, which
 721 often involve explosions in rapid succession (Dürig, Gudmundsson, Karmann, et al., 2015;
 722 Pistolesi et al., 2011). The results of this study provide insight on how to quantitatively
 723 interpret geophysical signals measured during such eruptions, as well as the resulting craters
 724 and deposits. They show that energy is a robust parameter to relate the transient, dy-
 725 namic phenomena, such as airborne and seismic pressure and stress waves and debris jets,
 726 with the long term products such as crater, subsurface deposits and ejecta. Finally, we
 727 emphasize that much of the presented physical signal analysis relies on (a) the high fre-
 728 quency records of airborne signal and (b) on the combination of relative near-field and
 729 far-field records. Deployment of such sensors hold promise for progress in seismo-acoustic
 730 volcano monitoring.

731 **Appendix A Depth- and Distance Dependency of Peak Pressures from**
 732 **Previous Experiments**

733 In previous blasting experiments (Ross et al., 2013; Graettinger et al., 2014; Valen-
 734 tine et al., 2015; Sonder et al., 2015), a set of uncalibrated microphones was placed ev-
 735 ery 5 m starting at 5 m to 30 m distance from the source. In all experiments the micro-
 736 phones were placed 10 cm above the ground facing towards the blast center. The blasts
 737 happened at various scaled depths with an emphasis roughly around optimum excava-
 738 tion conditions ($\bar{d} \simeq 4 \times 10^{-3} \text{ m J}^{-1/3}$), but also deeper and some shallower blasts. De-
 739 spite the uncalibrated pressure signal the raw signals were evaluated, since all sensors
 740 were of same model and therefore comparable. The result can be used to determine the
 741 relative depth dependency of impulse- and pressure signals, and compare them to other
 742 work (e.g. Ford et al., 2014). Signals were evaluated for peak pressure and impulse the
 743 same way as described for the here presented experiments in the main text.

744 Results show that the expected exponential depth dependency (Equation 11) un-
 745 derestimates both, pressure and impulse for deeper blasts (Figure A1). Therefore a sec-
 746 ond term that only depends on scaled distance was added to the combined depth- and
 747 distance dependencies

748
$$p_p(\bar{d}, \bar{r}) = \frac{C_{p,1}}{\bar{r}} e^{-\bar{d}/\bar{d}_{p,0}} + \frac{C_{p,2}}{\bar{r}} \quad , \quad (\text{A1})$$

749
$$\bar{I}(\bar{d}, \bar{r}) = \frac{C_{i,1}}{\bar{r}} e^{-\bar{d}/\bar{d}_{i,0}} + \frac{C_{i,2}}{\bar{r}} \quad . \quad (\text{A2})$$

 750

751 At scaled depths smaller than $1.2 \bar{d}_{\text{opt}} (\simeq 5 \times 10^{-3} \text{ m J}^{-1/3})$ the first term dominates, and
 752 the peak pressure show an exponential dependency (Figure A1). At larger scaled depths
 753 peak pressures decay slower than this exponential predicts. More research is necessary,
 754 to clarify the slow decay. Bowman et al. (2014) suggest that ground motion dominates
 755 the airborne signal at larger depths. Best fitting values for the depth decay constant in
 756 the exponential is for the pressure case $\bar{d}_{p,0} = (5.4 \pm 0.5) \times 10^{-4} \text{ m J}^{-1/3}$, and for the im-
 757 pulse case $\bar{d}_{i,0} = (1.1 \pm 0.3) \times 10^{-3} \text{ m J}^{-1/3}$. $\bar{d}_{i,0}$ deviates by about 12% from the value
 758 found by Ford et al. (2014) responsible for depth decay (\bar{d}_3 , Table C1). We interpret this
 759 as good agreement for the range $0 \leq \bar{d} \leq 5 \times 10^{-3} \text{ m J}^{-1/3}$.

770 **Appendix B Interpolation Constants of KG85 Pressure and Impulse**

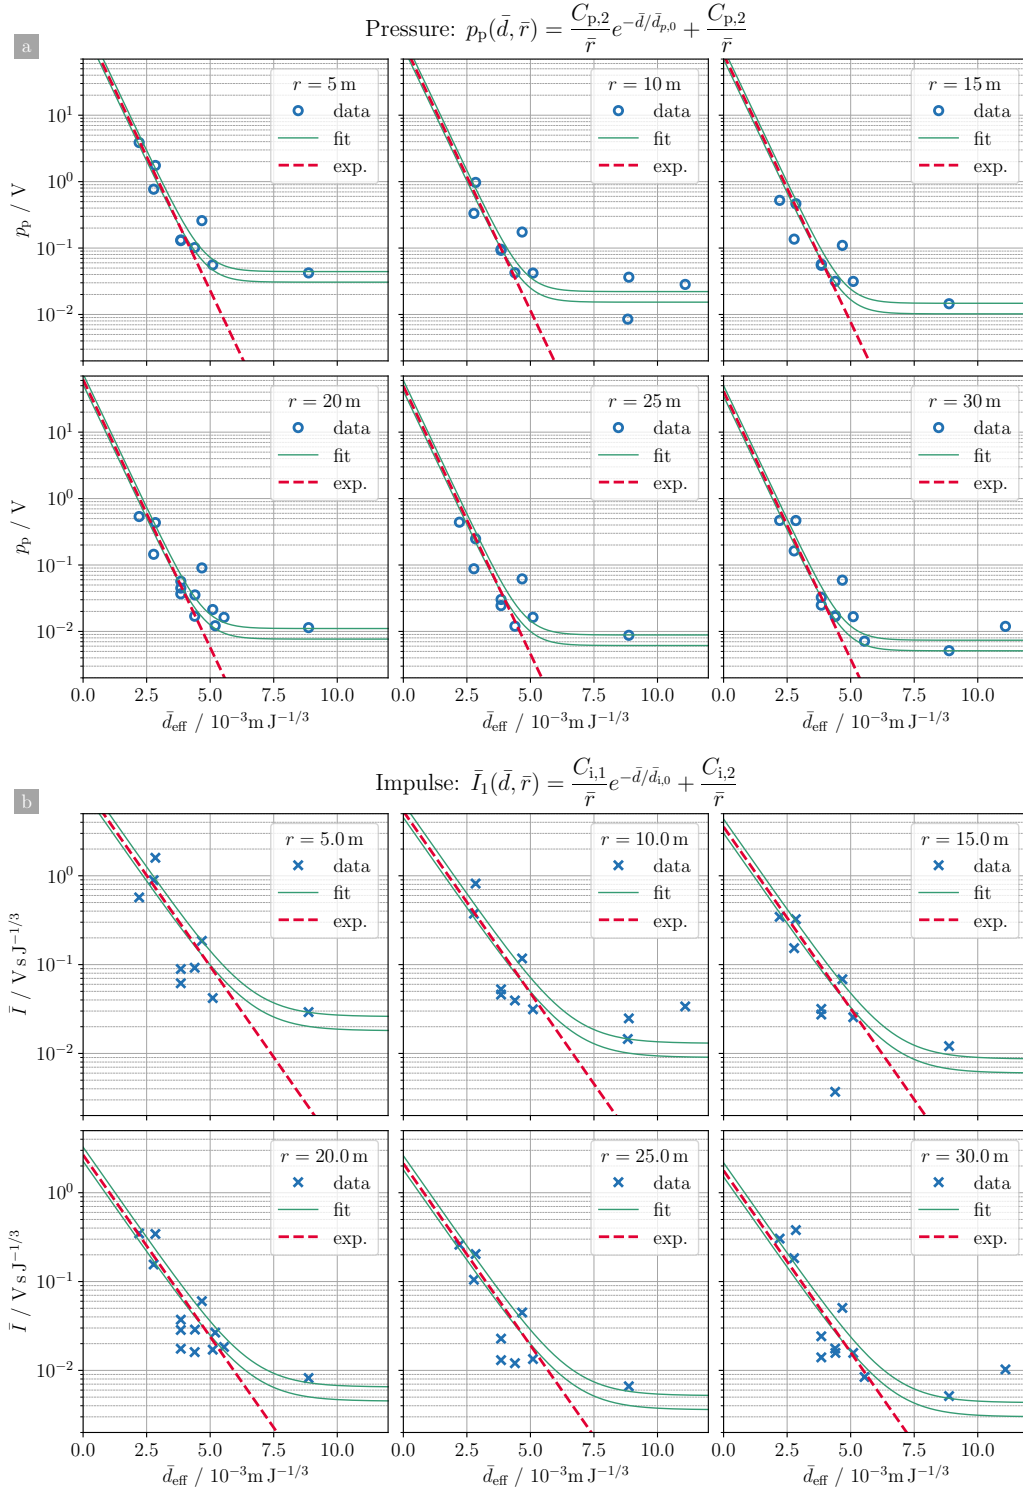

771 The empirical equations for dependencies of blast overpressure, scaled impulse and
 772 scaled blast duration on scaled distance are as follows.

773 Overpressure:

$$\bar{p} = \bar{p}_0 \frac{1 + \left(\frac{\bar{r}}{Z_{p,0}}\right)^2}{\sqrt{1 + \left(\frac{\bar{r}}{Z_{p,1}}\right)^2} \sqrt{1 + \left(\frac{\bar{r}}{Z_{p,2}}\right)^2} \sqrt{1 + \left(\frac{\bar{r}}{Z_{p,3}}\right)^2}} \quad (\text{B1})$$

774 Scaled impulse:

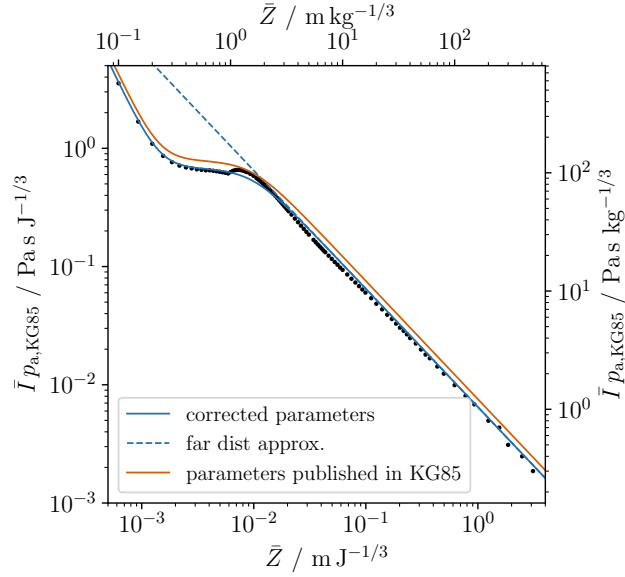

$$\bar{I}_1 = \bar{I}_0 \frac{\sqrt{1 + \left(\frac{\bar{r}}{Z_{I,0}}\right)^4}}{\left(\frac{\bar{r}}{Z_{I,1}}\right)^2 \left(1 + \left(\frac{\bar{r}}{Z_{I,2}}\right)^3\right)^{1/3}} \quad (\text{B2})$$

760

761 **Figure A1:** Peak pressure (a) and scaled impulse (b) of previous blast experiments,
 762 measured between 5 m and 30 m from the blasts. Pressures are shown in raw units (Volts).
 763 Depth dependencies are exponential for $\bar{d} \leq 5 \times 10^{-3} \text{ m J}^{-1/3}$. [Caption continues...]

765 **Figure A1:** [*Continued*] Peak pressure decays roughly double as fast compared to im-
 766 pulse ($\bar{d}_{p,0} = 5.4 \times 10^{-4} \text{ m J}^{-1/3}$, $\bar{d}_{i,0} = 11 \times 10^{-4} \text{ m J}^{-1/3}$). The red dashed lines are the
 768 exponentials $C_{p,1}e^{-\bar{d}/\bar{d}_{p,0}}/\bar{r}$ and $C_{i,1}e^{-\bar{d}/\bar{d}_{i,0}}/\bar{r}$, for pressure and impulse, respectively.
 769

779

780 **Figure B1:** Effect of corrected value for \bar{I}_0 on the interpolation curve (Equation B2).
 781 For a reason not known to the authors the original value for \bar{I}_0 (orange curve) does not
 782 fit the KG85 data (black dots) well. We used a changed value, which better fits this data
 783 (blue curves, Table B1).
 784

785

775 Scaled blast duration:

$$\bar{t}_d = \bar{t}_0 \frac{1 + \left(\frac{\bar{r}}{Z_{t,0}}\right)^{10}}{\left(1 + \left(\frac{\bar{r}}{Z_{t,1}}\right)^3\right) \left(1 + \left(\frac{\bar{r}}{Z_{t,2}}\right)^6\right) \left(1 + \left(\frac{\bar{r}}{Z_{t,3}}\right)^2\right)^{1/2}} \quad (\text{B3})$$

776 Values for the constants $Z_{x,y}$ are given in Table B1. For large distances, i.e. $\bar{r} \gg Z_{x,y}$
 777 the 1 in each of the factors in the above formulas becomes small when compared to the
 778 factor $\bar{r}/Z_{x,y}$ and can be neglected. Then \bar{p} and \bar{I} go with \bar{r}^{-1} :

$$\begin{aligned} \bar{p} &\sim \bar{p}_0 \frac{Z_{p,1} Z_{p,2} Z_{p,3}}{Z_{p,0}} \frac{1}{\bar{r}} = \frac{a_{p,\text{ref}}}{\bar{r}} \\ \bar{I} &\sim \bar{I}_0 \frac{Z_{I,1}^2 Z_{I,2}}{Z_{I,0}^2} \frac{1}{\bar{r}} = \frac{a_{I,\text{ref}}}{\bar{r}} \end{aligned} \quad (\text{B4})$$

Table B1: Constants for the empirical interpolation formulas for blast pulse overpressure, scaled impulse and scaled duration, in SI and kg-TNT equivalent units.

Constant SI		kg _{TNT}	Remarks
<u>Pressure</u>			
\bar{p}_0	8.08×10^2	8.08×10^2	Scaled length- and time units differ by a factor of the 1/3 power of 1 kg TNT explosive energy. $(E_{\text{kg TNT}})^{1/3} = (4.184 \times 10^6 \text{ J})^{1/3} = 161.1 \text{ J}^{1/3}$.
$Z_{p,0}$	$2.79 \times 10^{-2} \text{ m J}^{-1/3}$	$4.50 \text{ m kg}^{-1/3}$	
$Z_{p,1}$	$2.98 \times 10^{-4} \text{ m J}^{-1/3}$	$4.80 \text{ m kg}^{-1/3}$	
$Z_{p,2}$	$1.99 \times 10^{-3} \text{ m J}^{-1/3}$	$0.32 \text{ m kg}^{-1/3}$	
$Z_{p,3}$	$8.38 \times 10^{-3} \text{ m J}^{-1/3}$	$1.35 \text{ m kg}^{-1/3}$	
<u>Impulse</u>			
\bar{I}_0	$3.52 \times 10^{-7} \text{ s J}^{-1/3}$	$5.68 \times 10^{-5} \text{ s kg}^{-1/3}$	Original value for \bar{I}_0 from Kinney and Graham (1985) is $6.61 \times 10^{-5} \text{ s kg}^{-1/3} = 6.7 \times 10^{-2} \text{ bar ms kg}^{-1/3} / 1.01325 \text{ bar}$.
$Z_{I,0}$	$1.43 \times 10^{-3} \text{ m J}^{-1/3}$	$0.23 \text{ m kg}^{-1/3}$	
$Z_{I,1}$	$6.21 \times 10^{-3} \text{ m J}^{-1/3}$	$1.00 \text{ m kg}^{-1/3}$	
$Z_{I,2}$	$9.62 \times 10^{-3} \text{ m J}^{-1/3}$	$1.55 \text{ m kg}^{-1/3}$	
<u>Duration</u>			
\bar{t}_0	$6.08 \times 10^{-3} \text{ s J}^{-1/3}$	$0.980 \text{ s kg}^{-1/3}$	
$Z_{t,0}$	$3.35 \times 10^{-3} \text{ m J}^{-1/3}$	$0.54 \text{ m kg}^{-1/3}$	
$Z_{t,1}$	$1.24 \times 10^{-3} \text{ m J}^{-1/3}$	$0.02 \text{ m kg}^{-1/3}$	
$Z_{t,2}$	$4.59 \times 10^{-3} \text{ m J}^{-1/3}$	$0.74 \text{ m kg}^{-1/3}$	
$Z_{t,3}$	$4.28 \times 10^{-2} \text{ m J}^{-1/3}$	$6.90 \text{ m kg}^{-1/3}$	

Table C1: Constants for the empirical impulse scaling formula from Ford et al., 2014.

Constant		SI	kg _{TNT}
β_1		2.48	2.48
b_1	$b_1 = \frac{1 \text{ Pa s m}}{p_{a,\text{ref}}} \times \frac{10^{\beta_1}}{E_{\text{kg,TNT}}^{2/3}}$	$1.15 \times 10^{-7} \text{ s m J}^{-2/3}$	$1.85 \times 10^{-5} \text{ s m kg}^{-2/3}$
β_3		$3.46 \times 10^2 \text{ J}^{1/3} \text{ m}^{-1}$	$2.15 \text{ kg}^{1/3} \text{ m}^{-1}$
\bar{d}_3	$\bar{d}_3 = \frac{1}{\beta_3 \ln 10}$	$1.25 \times 10^{-3} \text{ m J}^{-1/3}$	$0.202 \text{ m kg}^{-1/3}$
$p_{a,\text{ref}}$		$1.01325 \times 10^5 \text{ Pa}$	$1.01325 \times 10^5 \text{ Pa}$
$E_{\text{kg,TNT}}$		$4.184 \times 10^6 \text{ J}$	1 kg

786 Appendix C Impulse Depth- and Distance Dependency

787 Ford et al. (2014) found the following model to fit scaled blast impulse, distance
788 and depth:

$$\log_{10} \bar{I} = \beta_1 + \log_{10} \bar{r} + \beta_3 \bar{h} - \log_{10}(1 + 10^{10\beta_3 \bar{h}})/10 \quad (\text{C1})$$

789 Here \bar{h} is the scaled height of burst, and energy was specified in kg TNT. Changing to
790 scaled depth of explosion ($\bar{d} = -\bar{h}$), this can be written as

$$\bar{I}_1 = \frac{b_1}{\bar{r}} \frac{e^{-\bar{d}/\bar{d}_3}}{(1 + e^{-10\bar{d}/\bar{d}_3})^{1/10}} \quad (\text{C2})$$

791 Constants b_1 and \bar{d}_3 are listed in Table C1. Ford et al. present the scaled impulse mul-
792 tiplied by ambient reference pressure, which is different from this study where scaled im-
793 pulse is scaled overpressure integrated over energy-scaled time. We note that for $\bar{d} =$
794 $\bar{h} = 0$ the depth dependent part reduces to $2^{-0.1} \simeq 0.93$, which is about 7% different
795 from an exponential ($e^0 = 1$). For larger depths this difference is smaller, which justi-
796 fies the use of an exponential depth part (Appendix A) without the reducing factor which
797 is necessary above the surface:

$$\bar{I} = \frac{b_1}{\bar{r}} e^{-\bar{d}/\bar{d}_3} \quad (\text{C3})$$

798 Acknowledgments

799 The authors acknowledge NSF grant EAR-1420455 for funding the necessary blasting
800 resources, and University at Buffalo for hosting a workshop during which experiments
801 were conducted. Kayley Diem-Kay, Norman Yu and David Hyman are acknowledged for
802 their assistance with experiment preparation and data recording.

803 The authors express appreciation to Kent Gee, Dept. of Physics and Astronomy
804 at Brigham Young University (BYU) for providing the equipment used for the broad-
805 band microphone measurements in this experiment. Funding for the BYU acoustical mea-
806 surement team’s participation came from the BYU College of Physical and Mathemat-
807 ical Sciences that funded six undergraduate research assistant: Sarah Ostergaard, Eric
808 Lynsenko, Grace McKay Smith, Christian Lopez, Carla Wallace, and Menley Hawkes;
809 and the NSF-funded research Experience for Teachers hosted at BYU that allowed mid-
810 dle school science teacher Julio Escobedo to play a pivotal role.

811 We thank Sean Maher and Richard Sanderson for their assistance with the seis-
812 mic and infrasound field instrumentation preparation and deployment. Matoza acknowl-
813 edges NSF grant EAR-1847736.

814 All measured data is hosted as datasets on VHub (vhub.org). A summarizing dataset
815 which makes all data available is available at <https://vhub.org/resources/4710>. Data
816 is also available separately as listed in the supporting information document (dataset S1).
