Abstract:

The November 15th, 2017 Mw 5.5 Pohang earthquake (South Korea) has been linked to hydraulic stimulation and fluid injections, making this the largest induced seismic event associated with an Enhanced Geothermal System (EGS). To understand its source dynamics and fault interactions, we conduct the first 3D high-resolution spontaneous dynamic rupture simulations of an induced earthquake. We account for topography, off-fault plastic deformation under depth-dependent bulk cohesion, rapid velocity weakening friction and 1D subsurface structure. A guided fault reconstruction approach that clusters spatio-temporal aftershock locations (including their uncertainties) is used to identify a main and a secondary fault plane which intersect under a shallow angle of 15°. Based on simple Mohr-Coulomb failure analysis and 180 dynamic rupture experiments in which we vary local stress loading conditions, fluid pressure, and relative fault strength, we identify preferred two fault plane scenarios that well reproduce observations. We find that the regional far-field tectonic stress regime promotes pure strike-slip faulting, while local

[i]also at Instituto Andaluz de Geofísica, Universidad de Granada, Spain; Departamento de Física Teórica y del Cosmos, Universidad de Granada, Spain; Physical Science and Engineering, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia

25   stress conditions constrained by borehole logging generate the observed thrust faulting component.

26   Our preferred model is characterized by overpressurized pore fluids, non-optimally oriented but

27   dynamically weak faults and a close to critical local stress state. In our model, earthquake rupture

28   "jumps" to the secondary fault by dynamic triggering, generating a measurable non-double couple

29   component. Our simulations suggest that complex dynamic fault interaction may occur during

30   fluid-injection induced earthquakes and that local stress perturbations dominate over the regional

31   stress conditions. These findings, therefore, have important implications for seismic hazard in

32   active geo-reservoir.

33

34   1. Introduction

35   The Korean Peninsula is known to have a rather low-level of seismicity (compared to

36   neighboring countries like China and Japan) because it lies on the continental margin of the east

37   Eurasian plate. However, on November 15th, 2017 (05:29:31 UTC), a magnitude Mw 5.5

38   earthquake occurred (hereinafter the Pohang earthquake), the second-largest recorded earthquake

39   in South Korea following the 2016 Mw 5.5 Gyeongju earthquake. The Pohang earthquake caused

40   one fatality, injured 82 people, and generated more than $300 millions in total economic loss

41   (Ellsworth et al., 2019; Lee et al., 2019). The hypocenter was located approximately 10 km

42   northeast of Pohang city, close to the Pohang Enhanced Geothermal System (EGS) site (36.106°N,

43   129.373°E and depth ~4.27 km, Korean Government Commission, 2019). Its proximity to the EGS

44   site and hypocentral depth similar to the open hole sections of the fluid-injection wells (Figure 1)

45   quickly raised questions if this earthquake is associated with EGS activities (Grigoli et al., 2018;

46   Kim et al., 2018).

47   The Pohang EGS project was designed to create an enhanced geothermal reservoir within

48   a low permeability crystalline basement. The basement is overlain by cretaceous volcanic and

49   sedimentary rocks, tertiary volcanic and sedimentary rocks, and quaternary sediments (Ellsworth

50   et al., 2019). During a period of four years (2012 to 2016), two geothermal wells, PX-1 and PX-2

51   (maximum depth ~4.3 km) were drilled for hydraulic stimulations. At the surface, both wells are

52   separated by only 6 m distance, increasing to a separation of 599 m at a depth of ~4300 m. For

53   well PX-1, the drilling was stuck at a depth of 2419 m, and hence side-tracked into west-northwest

54   direction. Well PX-2 experienced large mud loss in the depth interval 3830 - 3840 m, while

55   cuttings contain significant fractions of friable round-shaped mud balls typical for fault gouge

56   (Korean Government Commission, 2019; Ellsworth et al., 2019). In these geothermal wells, five

57   hydraulic stimulations were conducted between 29 January 2016 and 18 September 2018. During

58   this period, each hydraulic stimulation phase was associated with seismicity. The magnitudes

59   during and after stimulations reached up to $M_L \approx 3$, while events were distributed within a

60   restricted area close to the wells (Woo et al., 2019). The depth of the seismicity before the Pohang

61   earthquake spans the depth range 3.8 to 4.4 km, comparable with the open-hole section of the well

62   at ~4.3 km depth (Ellsworth et al., 2019).

63   Recent studies confirm that the Pohang earthquake was induced by hydraulic stimulation

64   and extensive fluid injection at this EGS site (Korean Government Commission, 2019; Ellsworth

65   et al., 2019; Woo et al., 2019; Kim et al., 2020). These activities are considered to have activated

66   the previously unmapped fault which was found to intersect well PX-2 at a depth of ~3.8 km.

67   Chang et al. (2020) point out that increased pore-pressure stressing due to multiple injection wells

68   at the Pohang EGS site may have contributed to the mainshock generation. However, it has been

69   argued that the size of fluid-injection induced earthquakes can be managed by controlling pressure,

70   rate, and location of fluid injection (Hofmann et al., 2019). Data-driven empirical and numerical

71   studies have shown that the largest induced earthquakes are bounded by a function of injected

72   volume (McGarr, 2014; Galis et al., 2017).

73   Grigoli et al. (2018) find a complex-source mechanism for the Pohang earthquake with a

74   significant non-double couple (non-DC) component. They hypothesized that this earthquake

75   involved failure on two different faults with slightly different focal mechanisms. In fact, in EGS

76   reservoirs with extensive fluid injection and hydraulic stimulation, earthquakes with pronounced

77   non-DC components may occur (Julian et al., 1998). Moreover, fluid injections may induce local

78   deviation of the stress state from the regional stress regime (Schoenball et al., 2014; Martínez-

79   Garzón et al., 2013; Martínez-Garzón et al., 2014). Therefore, we examine how regional and local

80   stress conditions acting on different fault models (single plane and two planes) determine the

81   dynamic rupture process that leads to a source mechanism with non-DC components.

82   Dynamic rupture modeling aims to reproduce the physical processes that govern how

83   earthquakes start, propagate, and stop for given stress and frictional conditions acting on fault

84   surfaces. The earthquake dynamics are then a result of the model's initial conditions, such as

85   geometry and frictional strength of the fault(s), the tectonic stress state, the regional lithological

86   structure, and a frictional constitutive equation. Jin and Zoback (2018) model coseismic fully

87   dynamic spontaneous fault rupture resulting from preseismic quasi-static loading exerted by fluid

88   perturbations in a faulted porous medium in 2D. Duan (2016) model 2D dynamic rupture

89   accounting for fluid effects of a propagating hydraulic fracture. Cappa and Ruitquist (2012) and

90   Buijze et al. (2017) constrain the onset of 2D dynamic rupture experiments by the stress state

91   resulting from solving a coupled quasi-static poroelastic equation. Further 2D studies that model

92   induced (not fully dynamic) earthquake rupture linked to separately treated fluid diffusion

93   including Galis et al. (2017); Kroll et al., (2017); Dieterich et al. (2015); Garagash and

94   Germanovich (2012); Richards-Dinger and Dieterich (2012); Viesca and Rice (2012). Using

95   modern numerical methods and advanced hardware, a high degree of realism can be reached to

96   explicitly model in 3D the highly non-linear dynamic rupture process (e.g., Heinecke et al., 2014;

97   Roten et al., 2014; Uphoff et al., 2017; Wollherr et al., 2019; Ulrich et al., 2019a, 2019b). The

98   modeling results include spatial and temporal evolution of earthquake rupture, surface

99   displacements, and ground shaking caused by the radiated seismic waves.

100   In this study, we investigate the dynamic rupture process under variable stress and fault-

101   geometry assumptions for the Pohang earthquake, using the high-performance-computing (HPC)

102   enabled software package SeisSol (https://github.com/SeisSol/SeisSol). Two alternative fault

103   geometries are considered, a one fault plane model (Model 1F) and a two fault planes model

104   (Model 2F). In our simulations, we consider a 1D velocity structure (Woo et al., 2019), off-fault

105   plasticity (Wollherr et al., 2018), depth-dependent bulk cohesion, a rapid velocity weakening

106   friction law, borehole estimates of stress, complex fault geometry, and high-resolution topography.

107   In the following, we first describe (Section 2) a new observationally guided fault

108   reconstruction approach based on spatio-temporal clusters of microearthquakes and their spatial

109   uncertainty. In Section 3, we analyse initial fault strength and loading stresses using static and

110   dynamic rupture modeling. We then compare the dynamics and kinematics of two preferred

111   models, Model 1F and 2F. The validation of Model 2F with regional waveforms, as well as

112   comparison of surface deformation between Model 1F and Model 2F are also presented in Section

113   3. Finally, we discuss the importance of considering local stresses loading, apparently weak and

114   critically stressed faults, overpressurized fluids, and dynamic multiple fault interaction in EGS.

115

2. Modeling Setup

In the following, we describe our approach to produce a physically viable model constrained by observational data. Dynamic rupture propagation is governed by fault strength, fault geometry, subsurface material properties, topography, loading ("initial") stresses, nucleation procedure, and empirical friction laws (Dunham et al., 2011a; Harris et al., 2011; Harris et al., 2018). Numerical experiments that vary the aforementioned parameters provide insights into fundamental earthquake physics as well as serve to identify preferred, self-consistent scenarios that explain the mechanical processes of the earthquake as well as observational data.

2.1 Fault reconstruction

The detailed fault geometry has a strong effect on the dynamic rupture process. Changes in strike, dip, and deviations from fault planarity can impact the rupture propagation and the corresponding physical processes. The Pohang earthquake occurred on one or several blind and unmapped fault(s). Because the unwrapped InSAR surface-displacement data show unclear fringes due to the small deformation around the epicenter (Choi et al., 2019; Song and Lee, 2019), we use the high-resolution earthquake catalog from Kim et al. (2018) to constrain the fault geometry based on a space-time (including their uncertainties in space) clustering approach. The earthquake catalog spans from 9 hours before to 3 hours after the mainshock and contains 217 events.

2.1.1 Spatio-temporal clustering

Clustering techniques allow deciphering complex fault structures by associating seismic events to groups (clusters), also discriminating events that are associated with the mainshock from uncorrelated earthquakes. We examine the seismic sequence to separate seismic clusters and

139   background events using nearest-neighbor distances following Zaliapin and Ben-Zion (2013). The

140   dependence of an event i to a parent event j is determined from the nearest-neighbor distance η_{ij}:

141

142    $$\eta_{ij} = dt_{ij} \times dr_{ij}{}^d , d_{ij} > 0; \eta_{ij} = \infty, dt_{ij} < 0 \qquad (1)$$

143

144   where $dt_{ij} = t_j - t_i$ is the time between event i and j, $dr_{ij} = (r_j - r_i)$ is the interevent distance

145   between events; r_i = coordinate of event i and r_j = coordinate of event j, and d is the fractal

146   dimension of the earthquake hypocenter distribution (Hirata, 1989). We find that the inferred

147   clusters are not very sensitive to the parameter d; hence we set $d = 1.6$ following previous studies

148   (Zaliapin and Ben-Zion, 2013; Zhang and Shearer, 2016; Cheng and Chen, 2018). Based on this

149   analysis, we find that all earthquakes of the catalog are part of the cluster and can be used for fault-

150   plane fitting (see Figure 2a). This cluster is characterized by interevent distances less than 1 km.

151

152   **2.1.2 Fault plane fitting**

153   We adopt the anisotropic clustering location uncertainty distribution (ACLUD) method, a

154   fault-network reconstruction approach introduced by Wang et al. (2013), which accounts for

155   uncertainties in earthquake locations. This method is extended by considering regional tectonic

156   constraints, focal mechanisms, and surface geological manifestation as prior information, leading

157   to the following improvements in the original ACLUD algorithm:

158   1) Initialize N_0 number of faults following the predefined orientation of the S_{Hmax} extracted

159   from the world stress map with random position and size.

160   2) For each cluster, if more than four similar focal mechanisms (strike, dip, rake) are available,

161   we use this information to separate events that have distinct focal mechanisms into other

162   clusters.

163   3) If surface geological manifestation (fault traces) exists (not the case for this study), the

164   strike and dip of the generated fault segment(s) should follow the closest interpreted fault

165   trace orientation.

166   We refer to this modified ACLUD method as guided-ACLUD (g-ACLUD).

167   All explored solutions are subject to a statistical validation process that examines the

168   likelihood of each proposed fault-network, given all available focal mechanisms. Statistical

169   validation uses the Bayesian Information Criterion (BIC). Initially, the method uses a random

170   number of fault planes. A single fault plane may be split if the BIC remains high. On the other

171   hand, two close-enough fault planes with similar orientation (strike and dip) may be merged into

172   a single fault plane. The process is repeated until the BIC reaches a pre-defined minimum or if the

173   process exceeds the maximum specified number of iterations (Wang et al., 2013).

174   The ACLUD algorithm by Wang et al. (2013) uses event locations and the associated

175   uncertainties given by the earthquake catalog. We incorporate additional information to increase

176   the robustness of the results and to decrease the explored parameter space. As *a priori* information,

177   we use the orientation of the maximum compressive regional stress given by the world stress map

178   (Heidbach et al. 2018) and available focal mechanisms in the area which are associated with the

179   earthquake catalog. Therefore, we use a maximum horizontal stress orientation of 74° with an

180   uncertainty of 25° and consider the focal mechanism inferred by Grigoli et al. (2018). Since

181   location errors are not specified in this earthquake catalog, we assume normally distributed

182   uncertainty for all events (standard deviation of 100 m). Note that Kim et al. (2018) obtained a

183   median error of 42, 31, and 36 m in the EW, NS, and vertical directions, respectively, but no

184   uncertainties for individual events.

185   Figure 2b, 2c, 2d show the g-ACLUD selected solution, characterized by the smallest BIC,

186   which features two intersecting planar fault planes. The main plane strikes at 214° and dips at 65°,

187   while the secondary fault plane strikes at 199° and dips 60°, respectively. The two fault planes are

188   separated by a narrow angle of 15°. The secondary fault aligns with the subsidiary fault plane

189   identified by Kim et al. (2018). The dimensions of the main and secondary fault planes are 4.3 x

190   2.8 km and 3.0 x 2.2 km, respectively. As the goal of this study is to compare the rupture process

191   for two different fault configurations, we define a one fault plane geometry (Model 1F) and a two

192   fault planes geometry (Model 2F; derived fault reconstruction analysis). The single-fault model

193   has a fault plane striking 214° and dipping 43°, as suggested by Korean Government Commission

194   (2019), Ellsworth et al. (2019), and Woo et al. (2019).

195

2.2 Material properties

197   We assume an elasto-plastic, isotropic medium based on the 1D velocity profile (Figure

198   S1a; Woo et al. (2019)). The velocity profile honors geological structures observed from drilling

199   cores and seismological observations from both active and passive sources, for instance, vertical

200   seismic profiling (VSP) and well logging (Korean Government Commission, 2019; Woo et al.,

201   2019). The density distribution (Figure S1a) is adopted from the report by Korean Government

202   Commission (2019).

203   We use a computationally efficient implementation of a Drucker-Prager off-fault

204   viscoplastic rheology (Wollherr et al., 2018). The off-fault failure criterion is based on the internal

205   friction coefficient (bulk friction) and bulk cohesion. We assume a constant internal friction

206 coefficient equal to the prescribed on-fault friction coefficient ($\mu_{bulk-friction} = 0.6$) for the entire

207 model domain. However, bulk cohesion is set to be depth-dependent, accounting for geologic

208 strata in the Pohang EGS site and the hardening of rocks with depth. Therefore, bulk cohesion

209 ranges from $c = 4$MPa near the surface to $c = 50$MPa at a depth of 6 km. A lower bulk cohesion

210 (12.5% of the surroundings) is applied in a 1.5 x 0.3 x 4 km^3 volume around the fault intersection

211 for the case of two fault planes to mimic pre-existing damage which enhances off-fault yielding

212 and to prevent unrealistic high on-fault stresses at the fault intersection. We assume initially

213 equivalent stresses acting on and off the fault. Finally, we set a constant, mesh-independent

214 relaxation time following the analysis by Wollherr et al., (2018) and chose T_V= 0.05 s, consistently

215 with choices made in previous studies (e.g. Ulrich et al., 2019a, 2019b).

216

217 **2.3 Fault strength and loading stresses**

218   To constrain the most viable principal stress component azimuth and the overall stress

219 regime, we extract information (e.g., S_{Hmax} orientation and fault strength) from laboratory and

220 field observation to then perform numerical experiments. We adopt a friction law with rapid

221 velocity weakening (adapted from Dunham et al., 2011a; see Appendix A1) which reproduces the

222 rapid friction decrease observed in laboratory experiments at co-seismic slip rates (Di Toro et al.,

223 2011).

224   We parametrize fault friction aiming for realistic levels of static and dynamic frictional

225 resistance and stress drop. All frictional properties are detailed in Appendix A1. We apply velocity

226 weakening ($b - a = 0.004$) across the fault (see Figure S1b) and velocity strengthening ($b - a =$

227 -0.004) to the uppermost part of the fault, which allows for a smoother termination of the rupture

228 there. The state evolution distance (L), initial slip rate (V_{ini}), reference slip velocity (V_0), steady-

229   state friction coefficient (f_0), and weakened friction coefficient (f_w) are constant and depth-

230   independent.

231   We follow the systematic approach of Ulrich et al. (2019a) to examine initial fault stress

232   and relative apparent fault strength combining data from observations, (e.g., seismo-tectonic

233   observations and fault fluid pressurization) and the Mohr-Coulomb theory of failure. This

234   workflow reduces the non-uniqueness in dynamic rupture modeling parameterization by assessing

235   that the stress state is compatible with the fault geometry and the fault-slip orientation (rake angle)

236   inferred from finite source or moment tensor inversion. Assuming an Andersonian stress regime

237   (one principal stress axis is vertical), only four parameters are sufficient to fully describe the stress

238   state and strength of the fault system: the azimuth of maximum compressive stress (S_{Hmax}), the

239   initial relative fault prestress ratio (R_0), the stress shape ratio (v), and the fluid pressure ratio (γ),

240   all detailed hereafter.

241   The Pohang EGS site is considered to be located within a strike-slip stress regime (Soh et

242   al., 2018, and references therein). This translates into the maximum principal stress being

243   horizontal ($s_1 = S_{Hmax}$, with principal stress components $s_1 > s_2 > s_3 > 0$) under Andersonian

244   stress. Previous studies examined the azimuth of maximum horizontal stress using different

245   methods, such as borehole and seismological techniques, e.g., stress inversion of focal mechanisms

246   (Kim et al., 2017; Lee et al., 2017; Lee, Hong, and Chang, 2017; Soh et al., 2018; Korean

247   Government Commission, 2019; Ellsworth et al., 2019). Soh et al. (2018) inferred S_{Hmax} from

248   focal mechanisms of earthquakes that occurred between 1997 and 2016 and determined a regional

249    $S_{Hmax} = 74°$. However, the earthquakes closest (~40 km) to the Pohang EGS site used in their

250   analysis are the 2016 Gyeongju event and its aftershocks. Based on borehole data, Kim et al. (2017)

251   and Lee, Shinn, et al. (2017) determined that S_{Hmax} at shallow depths (700 m to 1000 m) within a

252   10 km radius from the Pohang EGS is about 130°. In contrast, Ellsworth et al. (2019) and Korean

253   Government Commission (2019) inferred a critically stressed thrust faulting regime. This stress

254   state implies that the vertical stress is the least principal stress under Andersonian stress ($s_v = s_3$).

255   They inferred an S_{Hmax} orientation of $77 \pm 23°$ based on dipole sonic logging data. This

256   orientation is similar to the value of 74°given in the world stress map (Heidbach et al., 2018).

257   Using numerical simulations, we then assess how these loading-stress regimes for the

258   inferred fault geometry determine nucleation and rupture of the Pohang earthquake. The stress

259   shape ratio v enables a contrast of different stress styles by balancing the principal stress

260   amplitudes. It is defined as:

261

262       $$v = \frac{(s_2 - s_3)}{(s_1 - s_3)} \qquad\qquad\qquad (2)$$

263

264   For strike-slip regimes (s_2 vertical), $v < 0.5$ characterizes transpression, $v \approx 0.5$ corresponds to

265   pure strike-slip regime, and $v > 0.5$ characterizes transtension (Ulrich et al., 2019a). Soh et al.

266   (2018) ($v = 0.12$), Ellsworth et al., (2019) and Korean Government Commission (2019) ($v = 0.1$)

267   suggests a stress regime acknowledging transpression around the Pohang EGS site (note that they

268   use different definition of v).

269   The initial relative prestress ratio (R_0) describes the closeness to failure on a virtual,

270   optimally oriented fault. $R_0 = 1$ indicates a critical stress level on all optimally oriented faults. We

271   can characterize fault strength spatially by calculating the relative prestress ratio (R) on every

272   point of the fault. R denotes the ratio of potential stress drop $\Delta\tau$ with respect to breakdown strength

273   drop $\Delta\tau_b$ for given frictional cohesion (c), static (μ_s) and dynamic (μ_d) friction coefficient (e.g.,

274   Aochi and Madariaga, 2003) expressed as:

275

$$R \quad = \frac{\Delta\tau}{\Delta\tau_b} = \frac{\tau_0 - \mu_d \sigma_n}{c + (\mu_s - \mu_d) \times \sigma_n} \qquad\qquad (3)$$

277

278   where τ_0 and σ_n are initial shear and normal traction on the fault plane, respectively. However, in

279   this study, we neglect the contribution of frictional cohesion ($c = 0$), which is mostly important to

280   incorporate close to the Earth's surface. We assume $\mu_s = f_0 = 0.6$ and $\mu_d = f_w = 0.1$. The relative

281   prestress ratio can be related to the relative fault strength parameter (S) defined as $S = 1/R \quad -$

282   1. On-fault values of R change at every point as we vary R_0, taking on values $R \leq R_0$ depending

283   on the orientation of each fault point with respect to the optimal orientation.

284   The vertical principal stress is assumed to vary linearly with depth, consistent with the

285   geological strata (depth-dependent density (ρ) in Figure S1a). We assume the intermediate

286   principal stress component, s_2, to be vertical. The confining pressure of the overlying rock is

287   reduced by the pore pressure (P_f). We assume P_f proportional to lithostatic stress as $P_f = \gamma \rho g z$,

288   where g is the gravitational acceleration ($9.8\ m/s^2$), and z denotes depth (in meters) and γ is the

289   fluid pressure ratio. A fluid pressure ratio of 0.37 indicates hydrostatic pore pressure, while $\gamma >$

290   0.37 implies an overpressurized stress state.

291   We perform a range of static and dynamic numerical experiments described below to test

292   the sensitivity of the resulting dynamic rupture models to the chosen stress parameterization in

293   terms of S_{Hmax}, R_0 and γ. We keep the 4th parameter, the stress shape ratio, fixed at $v = 0.12$ (Soh

294   et al., 2018). We do not adjust the stress states for the stress excess during nucleation (see Appendix

295   A2). The overstressed nucleation and its parameters are constant for all 180 numerical

296   experiments.

297

3. Results

299   We use the open-source software SeisSol (details in Appendix A3, **numerical method**) to

300   solve the elastodynamic equations of motion for fault rupture under stress and friction acting on

301   the fault surface, coupled to seismic wave propagation in complex media. We set the on-fault mesh

302   size using estimates of cohesive zone width (details in Appendix A3, **mesh generation**). We

303   incorporate high-resolution topography into our modeling. Figure 3 shows the computational mesh

304   overlain by a snapshot of absolute velocity at t = 5 s.

305   Next, we present 3D dynamic rupture simulations for scenarios that consider one and two

306   intersecting fault planes, incorporating depth-dependent regional loading stresses, off-fault plastic

307   yielding, and high-resolution surface topography. In the preferred model (Model 2F), the

308   secondary fault plane is dynamically triggered and can explain the observed non-double couple

309   component of the moment tensor solution. Our model is compatible with regional waveforms and

310   surface deformation derived from published InSAR analysis.

311

3.1 Static and dynamic analysis of initial fault strength and stresses

313   We first constrain the regional stress from purely static analysis. Figure S2 shows a few

314   cases (out of many permutations (see also Table S1)) we analyzed. The six examples shown use

315   parameters $\gamma = 0.5$ and $R_0 = 0.7$, and variable S_{Hmax} in the range 52° - 140°. According to the

316   static analysis, $S_{Hmax} < 87°$ is insufficient to generate a rake angle of shear traction compatible

317   with the thrust-faulting component inferred by the focal mechanism and moment tensor solution.

318   At $S_{Hmax} \geq 87°$, a thrust-faulting component starts to emerge. Interestingly, only the secondary

319   fault plane features a rake angle larger than 40° for $S_{Hmax} = 77° - 140°$. A rake angle of ~ 80°,

320   obtained with $S_{Hmax} = 120°$, can potentially produce the thrust-faulting component inferred by

321 moment tensor solution. For this parametrization, the secondary fault plane reaches a higher rake

322 angle of approximately 110°.

323 We restrict the parameter space for R_0 and γ based on our static analysis. We then

324 systematically explore all permutations of the three different parameters within the selected range

325 using dynamic rupture simulations. We vary R_0 in the range 0.7 - 0.9, γ within 0.37 - 0.9 and S_{Hmax}

326 within 67 - 120°. Figure 4 summarizes the outcome of 180 numerical dynamic rupture

327 experiments. We find that under hydrostatic pressure ($\gamma = 0.37$), $S_{Hmax} = 120°$ generates self-

328 sustained ruptures over any other S_{Hmax} orientation.

329 The thrust-faulting component generated with $S_{Hmax} = 67° - 87°$ is insufficient to explain

330 the seismological observation using dynamic rupture modeling. Such S_{Hmax} leads to pure strike-

331 slip faulting as the only mechanical viable solution. Both dynamic and static analyses suggest that

332 $S_{Hmax} = 120°$ is necessary to generate a thrust-faulting component close to the observations. Our

333 analyses allow determining a preferred parameterization, compatible with inferred ground

334 deformation, observed regional waveforms, and the inferred focal mechanism: $R = 0.8$ and $\gamma =$

335 *0.5.*

336

337 **3.2 Rupture dynamics of the preferred scenario Model 1F and Model 2F**

338 Figure 5a and movie M1 (in supplementary material) provide an overview of the simulated

339 earthquake rupture of the preferred two fault model Model 2F: rupture propagates spontaneously

340 across the main fault plane and dynamically triggers the secondary fault plane (rupture jumping).

341 The rupture nucleates smoothly due to the prescribed time-dependent overstress (see

342 Appendix A2) centered at the hypocenter location; it then spontaneously propagates bilaterally

343 across the main fault plane. At a rupture time of 0.65 s, two successive slip-rate fronts emerge,

344   with lower peak slip rates than the main rupture front (Figure 5a, left). This rupture complexity is

345   associated with the simultaneous rupture on both fault planes, leading to multiple reflected and

346   trapped waves in-between the two fault planes, reactivating the main fault around the intersection.

347   Rupture complexity decreases as rupture on the secondary fault plane terminates. After rupture

348   time t = 0.75 s, we observe solely pulse-like rupture propagation across the main fault.

349   The secondary fault plane is dynamically triggered at 0.4 s and its rupture terminates at 0.8

350   s simulation time, while the main-fault is fully ruptured in about 1.1 s. The secondary fault plane

351   is only partially ruptured because the northern part of the main fault does not slip. High slip-rates

352   ($\sim$ 10 m/s) and multiple rupture fronts occur near the fault intersection at the secondary fault.

353   Rupture heals close to the fault intersection region around $t = 0.65 \ s$.

354   After $t = 0.75 \ s$ rupture on the main fault dynamically clamps (e.g., Kyriakopoulos et al.,

355   2019) and thus does not facilitate direct branching to the northern unbroken part of the secondary

356   fault plane. We observe asymmetric peak slip-rate distribution (see Figure S3), with higher values

357   on the single fault plane part of the network (Figures 5a, right) and lower peak slip rates where

358   ruptures across directly adjacent fault planes interact, which is also associated with high off-fault

359   plastic yielding (see section **Off-fault deformation** below). The entire rupture is completed after

360    $\sim$1.5 s simulation time, breaking 4 km of fault length and generating a moment magnitude of M_w

361   5.59 (dominated by slip on the main fault plane). We find that rupture stops smoothly and

362   spontaneously on the secondary fault plane and north-eastern part of the main fault plane, while

363   being stopped abruptly by the southwestern fault end of the main fault plane.

364   In contrast to the Model 2F, the one fault plane preferred Model 1F produces symmetric

365   bilateral slip-rate and slip distributions.

366

3.3 Rupture kinematics of the preferred Model 1F and Model 2F scenarios

Due to the size of the event and limited available data, the kinematics of the Pohang earthquake are challenging to characterize and explain. We here describe the model kinematics of the preferred Model 1F and Model 2F earthquake scenarios. and compare both with two observational studies (Song and Lee, 2019; Grigoli et al., 2018).

Song and Lee (2019) estimated the static slip distribution by InSAR (both descending and ascending-descending orbit) for a single fault plane with patch size 0.5 by 0.5 km. Higher slip predominantly occurs northeast of the hypocenter, with an average slip of 0.15 m (Song and Lee, 2019). Grigoli et al. (2018) applied an Empirical Green's Function (EGF) technique to study rupture duration and directivity, suggesting an apparent rupture duration of ~1s and ~3 s for stations observed in the SE and NW direction, respectively. Their focal mechanism shows an average rake of ~135°.

Both preferred scenarios vary slightly in moment magnitude, M_W 5.63 and M_W 5.59 for Model 1F and Model 2F, reflecting different fault geometries while otherwise using the same dynamic rupture model parametrization. We point out that most slip of Model 2F occurs on the main fault - its magnitude is reduced to M_W 5.51 when removing the subsidiary plane.

The resulting synthetic source time functions of Model 1F and Model 2F are presented in Figure 7a and 7b, respectively. The boxcar shaped moment rate function of Model 1F results from its comparably simple rupture dynamics across one planar fault. Model 2F features a more complicated moment rate function featuring two peaks of which the first one is reached at t = 0.5 s simulation time during simultaneous rupture of both fault planes. The rupture duration of both scenarios is less than 1.5 s. The moment tensor representations of Model 1F and Model 2F are presented in Figure 7c and 7d, respectively. Both scenarios show oblique faulting mechanisms.

390   Model 1F clearly produces a double-couple moment tensor solution (Figure 7c), whereas the

391   Model 2F yields a non-double couple solution due to complex source mechanism (Figure 7d), in

392   agreement with Grigoli et al. (2018). Nevertheless, our simulation produces a smaller amount of

393   CLVD (compensated linear vector dipole) compared to Grigoli et al. (2018). In fact, the equivalent

394   moment tensor solution of Model 2F can be decomposed, following the methodology of Vavryčuk

395   (2015), into 82.95% DC, -5.05% CLVD, and -12% isotropic (ISO) components. In contrast,

396   Grigoli et al. (2018) find -37% CLVD. In our simulations, Model 2F's rupture is characterized by

397   an average rupture speed of $v_r \approx$ *2,250 m/s*, well below the average Rayleigh wave speed at the

398   depth of the faults ($v_r \sim$ *0.75V_S*). The spatial variation of v_r is mainly related to the complexity of

399   rupture around the intersection for both, the main and secondary fault plane. We observe higher

400   average rupture speed $v_r \approx$ *2,780 m/s* ($v_r \sim$ *0.8V_S*) on the secondary fault plane (see rupture

401   contours every 0.2 s in Figures 5a, 5b). We note the localized occurence of supershear rupture

402   speeds ($\sim$ *4000 m/s*) near the edge of the prescribed nucleation patch of the main fault reflecting

403   the high overstress required for initiating the preferred rupture dynamics in our setup. Also, the

404   secondary fault plane features localized supershear episodes ($\sim$ *3800 m/s*). In our model setup,

405   this may be translated into locally high fluid overpressure, and/or reflect the low resolution and

406   1D restriction of the used velocity model. More complex fluid effects have been shown to

407   transition sub-rayleigh to supershear ruptures in fully coupled 2D models by Lin and Zoback

408   (2018).

409   In our preferred model, high slip ($\sim$ *2 m*) occurs in the center of the main fault. We observe

410   a maximum slip of 1.3 m at the secondary fault plane (Figure 6b). In total, the average on-fault

411   slip is 0.32m. Both, Model 1F and Model 2F, feature higher slip than Song and Lee (2019) infer

412   in their static slip inversion. In addition, differences may arise due to different modeling

413   assumptions in terms of fault dimensions and shear moduli. First, Song and Lee (2019) assume a

414   slightly larger shear modulus of G = 30 GPa than in our model (G = 26 GPa). Second, they assume

415   a single fault plane of significantly larger dimensions (6 x 5 km) than the faults of our models (see

416   section **Fault reconstruction**). This large fault geometry allows for the possibility of near-surface

417   slip.

418   The orientation of fault slip is modulated by the dynamic source process. The dynamic

419   interaction of the two fault planes induces a moderate thrust-faulting component (rake ~ *135° −*

420   *150°*) on the main fault plane, as well as complex time-dependent rake orientations on the

421   secondary fault (see also Figure 6c, 6d). In contrast to Model 2F, the orientations of the final rake

422   angle of Model 1F are distributed homogeneously, on average at 127°. The rake of Model 1F is

423   different from Model 2F due to different dip angles of the main fault which dips at 43° in Model

424   1F. This average rake angle is comparable to the focal mechanism derived by Grigoli et al. (2018).

425   The average on-fault slip is 0.35 m. We observe that, on average, the rupture speed is $v_r \approx$

426   *2400*m/s. Reflecting similar dynamic parameters to Model 2F, Model 1F also experiences

427   supershear rupture near the nucleation patch.

428

429   **3.4 Waveform comparison for Model 1F and Model 2F**

430   In the following, we analyze the differences between Model 1F and Model 2F in terms of

431   near and far-field ground motion. Hereinafter, all distances from the fault are considered as Joyner-

432   Boore distances (R_{JB}, the shortest distance from a site to the surface projection of fault planes).

433   We compare synthetic waveforms computed for hypothetical ("virtual") stations located close (~4

434   km) and far (>20 km) from the epicenter.

435   Figure 8b shows three-component waveforms at 19 randomly located virtual stations

436   (Figure 8a). We place 10 stations near the epicenter (~4 km horizontal distance) to inspect near

437   field seismic waveform characteristics. We filter all synthetic waveforms within the frequency

438   band of 0.1 - 2 Hz using a fourth-order Butterworth filter. Figure 8c depicts all 3-component

439   velocity waveforms. Overall, waveforms of scenarios Model 1F and Model 2F are very similar in

440   this frequency range, but waveforms from Model 1F have systematically higher amplitudes than

441   Model 2F. The most remarkable amplitude differences occur on the EW component for stations

442   004, 008, 009, and 010, which are all located above or close to the faults.

443   At some stations, distinct waveform differences appear (e.g., the NS-component of stations

444   007, 014, 011, and 019). Most of these stations are located on the hanging wall. After five seconds,

445   once the rupture is fully arrested, differences vanish, and the waveforms become comparable for

446   both models. As depicted in Figure 8b, the stations located close to the region where faults overlap

447   in Model 2F show significant differences in seismic wave signatures on the horizontal components.

448   One possible explanation may be that the additional secondary fault defocuses ground motions.

449

450   **3.5 Off-fault deformation**

451   Our preferred dynamic earthquake rupture model 2F reveals significant off-fault plastic

452   deformation in the vicinity of geometric fault complexity, similar to scenarios of the 1992 Landers

453   earthquake (Wollherr et al., 2018), the 2016 Kaikoura earthquake (Klinger et al., 2019) and the

454   2019 Ridgecrest earthquake sequence (Taufiqurrahman et al., 2019). Here, significant off-fault

455   plastic deformation (quantified as the scalar quantity η following Ma, 2008 and Wollherr et al.,

456   2019) occurs (i) in the pre-existing damage zone at the fault intersection, (ii) at the dilatational side

457   of the main and the secondary fault as expected from previous theoretical and numerical studies,

458 given the shallow angle of both faults and S_{Hmax} (Templeton and Rice, 2008; Gabriel et al., 2013),

459 and (iii) close to the free-surface (see Figures S3c and S3d).

460   The fault intersection of Model 2F elevates the total off-fault plasticity response

461 regularizing high on-fault stresses while limiting peak slip rates and reducing peak ground motions

462 (Andrews 2005; Dunham et al. 2011a; Gabriel et al., 2013; Roten et al., 2014; Wollherr et al.,

463 2018). When comparing waveforms, we indeed notice overall lower velocity amplitudes compared

464 to Model 1F in the surrounding stations of the fault planes caused by the combined effects of fault

465 complexity and off-fault yielding. Interestingly, the stronger plastic yielding response in model 2F

466 leads to lower variability (not shown here) in ground motions (PGV) (as in Wollherr et al., 2019)

467 even though the fault geometry is more complex.

468

469 **3.6 Model 1F and Model 2F surface deformations**

470   Next, we compare the co-seismic surface displacement generated by Model 1F to Model

471 2F (Figure 9a, 9b). We translate the synthetic vertical and horizontal displacements into Line-of-

472 sight (LoS) displacement components.

473   The spatial distribution of the co-seismic surface deformations is noticeably different.

474 Model 1F features higher LoS displacements in southeastern direction relative to the Gokgang

475 Fault (~ *2 km* from the bay) compared to Model 2F (~ *5 km* from the bay) and generates on

476 average lower negative LoS displacements. Model 1F creates a wider area of uplifted LoS

477 displacements, which resembles an ellipse with a major axis of 6 km and a minor axis of 4.1 km.

478 The most prominent spatial differences are (i) the vertical LoS displacements of Model 1F are

479 slightly migrated to the East relative to the epicenter and (ii) the location of zero displacements in

480 between vertical LoS displacements (in the region of the epicenter) and negative LoS

481   displacements at the eastern-to-southward of the epicenter. Model 2F produces an average of 5 cm

482   subsidence whereas Model 1F only produces 2 cm average subsidence. This can be attributed to

483   Model 1F's more shallow dipping angle. The co-seismic surface displacements of Model 2F

484   compare better than those of Model 1F to InSAR ground deformation inferences of Song and Lee

485   (2019), in terms of the location of the pivot line delimiting positive and negative LoS

486   displacements (~ *4.5 km* from the bay).

487   While synthetic (Model 2F) and observed surface displacements significantly differ locally

488   and quantitatively, they reveal qualitatively comparable large-scale features. The following

489   observations are captured by Model 2F: (i) Uplift/easting displacement is observed near the

490   epicenter and (ii) the uplifted area forms an ellipse-like shape with a major axis of ~5.6 km and a

491   minor axis of ~3.8 km. Correspondingly, Pohang city also experienced subsidence according to

492   field observations (Kang et al., 2019a, Kang et al., 2019b). Additionally, our synthetics also

493   suggest subsidence underneath the bay.

494   Although the contribution of the secondary fault plane is critical to reproduce the inferred

495   non-DC component, comparison of synthetic co-seismic surface displacements of Model 2F with

496   and without the secondary fault (see Figure S5a) suggests that the contribution of the secondary

497   fault plane to the ground displacement is small (Figure S5b), as expected from its small slip

498   contribution. We note that the InSAR data may not be sensitive enough to discriminate between a

499   one and a two-fault plane model.

500

501   3.7 Model 2F validation by regional waveform modeling

502   Unfortunately, a local seismic network of eight portable seismic stations (Kim et al., 2018)

503   deployed around the EGS site produced saturated (clipped) seismograms. Therefore, we choose to

504   compare synthetic waveforms to regional recordings at five stations surrounding the Pohang EGS

505   site (see Figure 1) at epicentral distances of approximately 70 km.

506   Model 2F compares well to regional low-frequency seismic wave observations (Figure 8c).

507   Synthetic waveforms are calculated using a Green's function database of teleseismic waveforms

508   (Instaseis, Krischer et al., 2017). We translate the dynamic rupture model into a single moment

509   tensor representation following Ulrich et al. (2019a, 2019b). The Green's function database we

510   use is based on the anisotropic Preliminary Reference Earth Model (PREM), and is accurate to a

511   maximum period of 2 s. Synthetic and observed waveforms are filtered using a 0.033 - 0.08 Hz

512   4th order Butterworth filter, equivalent to the frequency band used in the source inversion of Grigoli

513   et al. (2018). The goodness of fit is assessed by the root-mean-square (rms) misfit.

514   Although the synthetic waveforms compare reasonably well to regional recordings, we find

515   that a few synthetic amplitudes are systematically larger than the observed data. We attribute this

516   to the usage of a 1D PREM model, which is more suitable for modeling synthetics at larger

517   azimuthal distance. Additionally, the fact that our simulation returns a slightly higher seismic

518   moment than observed and is not able to capture the full non-DC component of the source may

519   play a role. In particular, the large misfit at Station TJN on the UD and EW component may be

520   attributed to unmodeled site effects. Our synthetics do not differ significantly from the synthetics

521   of Grigoli et al. (2018), derived by full-waveform inversion of the waveforms recorded at stations

522   BUS2, CHJ2, and NAWB. A significant difference is only noticeable on the NS component of

523   station BUS2 (south of the epicenter, Figure 1).

524

525   # 4. Discussion

526   ## 4.1 The importance of local stresses for rupture dynamics in EGS

527   The inferences of previous studies vary in terms of stress regimes and maximum horizontal

528   stress orientation around the Pohang EGS site, thereby motivating our systematic numerical

529   experiments as detailed in section **Static and dynamic analysis of initial fault strength and**

530   **stresses** under various loading stress settings. Assuming an Andersonian stress regime, we find

531   that an initial stress state constrained by regional stress inversions is unable to generate the

532   observed thrust-faulting component of the Pohang earthquake. This suggests important local

533   deviations from the regional stress state near the Pohang EGS site. Kim et al. (2017) and Lee et al.

534   (2017) infer the stress orientation at short epicentral distance (< 10 km) from borehole image log

535   data acquired prior to the Pohang earthquake. However, this data is limited to 1 km depth, whereas

536   the Pohang earthquake hypocentral depth is inferred to be deeper, at a depth of 4.27 km. Ellsworth

537   et al. (2019) noted that the in-situ stress state at the Pohang EGS site is transpressional.

538   From our static numerical experiments, we infer that a pure strike-slip stress regime ($s_2 =$

539   s_v) and $S_{Hmax} = 120°$ yield a thrust-faulting component consistent with observations (Figure S2).

540   This finding is corroborated by our dynamic rupture simulations under identical loading (Figure

541   7c, 7d). We also observe that under these conditions spontaneous rupture propagation is favoured.

542   The reverse faulting regime ($s_3 = s_v$) accounting for low $v = 0.1$ was also explored. However,

543   such reverse-stress regime, as suggested by Ellsworth et al. (2019), across the entire fault planes

544   does not yield sufficiently high shear tractions on our fault system - and dynamic rupture dies out

545   quickly.

546   Local variations of the stress state around EGS sites, including the Pohang EGS site, have

547   been observed in hydraulic stimulation experiments of crystalline-rock reservoirs (Schoenball et

548   a., 2010), data-driven geomechanical analysis (Ceunot et al., 2006; Hardebeck and Michael, 2006;

549   Martínez-Garzón et al., 2013; Martínez-Garzón et al. 2014; Schoenball et al., 2014) and numerical

experiments (Jeanne et al., 2015; Ziegler et al., 2017). Such spatial and temporal stress reorientation is typically a direct response to hydraulic stimulation and fluid injections (Cornet et al., 2007; Schoenball et al., 2010; Schoenball et al., 2013; Ziegler et al., 2017, Liu and Zahradnik, 2019). In the geothermal field surrounding the Geysers in California, Martínez-Garzón et al. (2014) found that the stress regime changed from normal-faulting to strike-slip near the injection wells. At the Pohang EGS site, local variations in the stress regime have been inferred from focal mechanisms of microearthquakes before and after the Pohang earthquake. Woo et al. (2019) reported strike-slip faulting north from the hypocenter to strike-slip associated thrust-faulting and pure thrust-faulting components towards the South before the mainshock. After the mainshock occurred, aftershock focal mechanisms were mainly strike-slip in the SW to oblique faulting in the NE (Kim et al., 2020). Changes in the stress orientation and regime near the hypocenter prior to the mainshock could correspond to hydraulic stimulation and fluid injections (Martínez-Garzón et al., 2014; Liu and Zahradnik, 2019). However, the aftershock source characteristics are probably related to co-seismic stress rotation.

Based on our analysis of various numerical experiments, we deduce that our models are highly sensitive to variations in the initial stress state, and therefore allow to finely constrain the fault stress loading parameters. For example, a small change in S_{Hmax} may induce a significant change in the modeled focal mechanism. All faults are exposed to the same local stress regime while experiencing varying ratios of shear and normal loading depending on their orientation towards this loading. Even a small change in fault geometry (e.g., in strike, dip, size, and the angle between fault planes) strongly affects the dynamic rupture result (e.g., Yamashita and Umeda, 1994; Aochi et al., 2005; Bhat et al., 2007; Ulrich et al., 2019a; van Zelst et al., 2019), as here illustrated when comparing Model 1F and Model 2F. We point out that trade-offs between the

573   inferred stress state and fault geometry can be readily explored if new observations become

574   available.

575   In summary, these observations support our assumption on the loading stress, which is

576   consistent with Ellsworth et al. (2019) in the nucleation region, but differently oriented everywhere

577   else. Complexities in the in-situ stress state are expected in the region where the Pohang earthquake

578   occurred, due to the history of hydraulic stimulations, that is, the EGS operation itself perturbs the

579   local stress conditions in a manner that makes it more difficult to assess the potential seismic

580   hazard implication (that are usually studied in advance and utilize regional stress information).

581

582   **4.2 The importance of critically stressed, static and dynamic weak faults and**

583   **overpressurized fluids**

584   Our experiments (Figure 4) emphasize the necessity of assuming overpressurized fluids

585   ($\gamma > 0.37$) and a close to critical stress state when assuming strong frictional weakening on the

586   fault(s). A critically stressed state has been suggested by Ellsworth et al. (2019) by analyzing

587   dipole sonic logging data at the Pohang drilling site. In our preferred Model 2F, we use the ratio

588   of shear over effective normal stress (τ/σ_n) to quantify fault strength, and find 0.54 and 0.59 for

589   the main and secondary fault plane, respectively. This fault strength is close to the assumed steady-

590   state friction coefficient ($f_0 = 0.6$) which indicates that the faults are close to failure prior to

591   rupture nucleation and thus close to critically stressed.

592   In our preferred model both faults are non-optimally oriented with respect to the local stress

593   conditions. The relative prestress ratio R is 0.35 on the main fault and 0.4 on the secondary fault

594   plane, which is less than our assumed $R_0 = 0.8$. According to Andersonian faulting theory, the fault

595   strength is related to its orientation with respect to the regional stress. Here, the main fault plane

596   is oriented at 54° and the secondary fault at 60° relative to the regional maximum compressive

597   stress (S_{Hmax} = 77°). Thus, the two fault planes system would be considered weak in the classic,

598   static sense.

599   All modeled faults in this study weaken dramatically at co-seismic slip rates while stress

600   drops are limited by the elevated fluid pressure. Besides resembling the dramatic friction decrease

601   observed in laboratory experiments and the theory of thermal weakening processes, previous

602   dynamic rupture studies utilizing rapid velocity weakening with low values of fully weakened

603   friction coefficient (f_w) reproduced rupture complexities, such as rupture reactivation and pulse-

604   like ruptures, without assuming small-scale heterogeneities.

605   In our simulation, we use a fluid pressure ratio of 0.5 which corresponds to a reduction of

606   the normal stress of approximately 14.3 MPa compared to a hydrostatic state. The reduction in

607   effective normal stress mechanically lowers the static strength of faults. Our assumption of high

608   fluid pressure may relate to various episodes of drilling mud loss on 30-31 October 2015 at 3800

609   m depth suggesting an increase of fluid pressure on the order of 20 MPa around the borehole, and

610   the fluid injection operations (Ellsworth et al., 2019; Korean Government Commission, 2019).

611

612   **4.3 The importance of fault interaction for the dynamic rupture process and**

613   **faulting mechanism**

614   In our preferred model, the secondary fault is only partially ruptured during the Pohang

615   earthquake. Strong variations in slip rate associated with dynamic rupture complexity across the

616   two faults planes and their interaction, spontaneous rupture arrest and the asymmetrically

617   accumulated fault slip on the main and secondary fault plane, could potentially favor dynamic and

618   static Coulomb stress transfers enabling a later activation of the unruptured area of the secondary

619   fault. The largest aftershock that occurred less than three hours after the mainshock at 650 m

620   epicentral distance to the northwest with respect to the mainshock may have occurred in such an

621   unruptured area on the secondary fault.

622   In our model, complex shear faulting across two fault planes induces a non-DC component,

623   which is, nevertheless, considerably smaller (14%) compared to the CLVD component inferred by

624   Grigoli et al. (2018). Additional factors not considered in this study may contribute to an apparent

625   non-DC component, such as strong deviations from fault planarity (larger scale curvature and

626   small-scale roughness, e.g., Bydlon and Dunham, 2015; Shi and Day, 2013; Ulrich and Gabriel,

627   2017; Mai et al., 2018), stronger heterogeneities in fault stress and strength (Ripperger et al., 2008)

628   and 3D subsurface structure (e.g., Pelties et al., 2015) increasing rupture complexity, as well as

629   incorporating tensile faulting, poroelastic rheology, and source or propagation anisotropy (Julian,

630   1998; Boitz et al., 2018). The CLVD contribution may also increase when assuming a larger

631   number of faults. While the limited data available does not suggest rupture of additional fault

632   planes, stochastically distributed and dynamically activated fracture networks (e.g., Okubo et al.

633   2019; Anger and Gabriel, 2019) around the main fault are expected given the on-going stimulation

634   operation.

635

636   **4.4 Importance of dense seismic monitoring during EGS projects**

637   The complex interaction of local stress loading and fault strength conditions, rupture

638   dynamics and fault interaction on multiple fault segments presented here highlights the importance

639   of a dense local seismic network within the operational areas for monitoring and analyzing

640   microseismicity before, during, and after EGS operation, to thereby mitigate the potential seismic

641   hazard. Pre-EGS stimulation seismic monitoring is needed to define the 'unperturbed state' of the

642 system (the rock volume to be stimulated) and for characterizing potentially unmapped fault(s)

643 that may interact during cascading rupture; such seismic monitoring may be accompanied by

644 detailed borehole logging to assess the local stress state prior to stimulation.

645   During the stimulation and operational phase, a dense seismic monitoring network is also

646 needed to facilitate high-precision and high-fidelity seismic source studies. In conjunction with

647 detailed operational fluid-injection parameters, the reservoir stress state and its susceptibility for

648 generating earthquakes can be assessed (Galis et al., 2017; Kwiatek et al., 2019). In fact, the

649 available recordings of the operational monitoring seismic network near the Pohang EGS site were

650 saturated (clipped) by the unexpected high magnitude earthquake, thus accelerometers would be

651 useful as complementary instruments in EGS monitoring networks. In addition, the rise of

652 Distributed Acoustic Sensing (DAS) opens new opportunities as an additional seismic monitoring

653 network especially for EGS that is located in urban areas (Zhan, 2019).

654   Our study suggests that fully physics-based numerical simulations prior, during and after

655 an EGS project may be useful to not only gain a first-order understanding of potential effects and

656 consequences of the EGS experiments (e.g., risk-prone area as reflected by peak ground motions

657 (PGVs, Figure S6)), but also to optimally design the seismic monitoring network to ensure that all

658 vital data are collected as needed for future monitoring and mitigation purposes.

659

660 5. Conclusions

661   A guided fault reconstruction approach that clusters spatio-temporal aftershock locations

662 accounting for their uncertainty is applied to create a two fault planes dynamic rupture model

663 which reproduces key characteristics of the Pohang earthquake. Rupture complexity is arising from

664 the dynamic interaction of two failing fault planes with shallow intersection angles.

665   Static Mohr-Coulomb failure analysis and 180 numerical simulations demonstrate that the

666   regional loading stress is unable to generate dynamic rupture consistent with the observed faulting

667   style. Resolving the regional tectonic stress field onto one fault of a geometry as suggested by

668   Korean Government Commission (2019), Ellsworth et al. (2019), and Woo et al. (2019) or onto

669   the reconstructed two fault planes leads inevitable to pure strike-slip faulting, in stark contrast to

670   the observed thrust-faulting mechanism. Instead, local stress variation relative to regional stress

671   orientation is needed to generate oblique faulting. We conclude that regional-stress orientation

672   may be misleading when assessing propensity for failure; this has important implications for

673   seismic hazard assessment. Also, overpressurized pore fluids, non-optimally oriented and

674   dynamically weak faults and a close to critical local stress state play major roles for our dynamic

675   rupture models of the Pohang earthquake. Such factors may be assessed when planning and

676   conducting EGS-type experiments, explorations, and operations.

677   Our dynamic rupture simulations reveal dynamic triggering from the main fault plane to

678   the secondary fault plane without direct rupture branching but via "rupture jumping". The

679   preferred two fault plane simulation compares well to regional observed data such as moment

680   release and far-field seismic waveforms. The single fault plane model, on the other hand, is unable

681   to reproduce the observed non-DC focal mechanisms and surface displacement distributions due

682   to simplicity of the dynamic rupture process and a shallower dip angle, respectively. Dynamic fault

683   interaction, amplified by rapid stress changes due to seismic waves reverberating between the two

684   fault planes, are needed to reproduce observations of a strong CLVD component. However, two

685   simultaneously breaking fault planes cannot fully explain the observed source complexity.

686   We demonstrate the maturity and feasibility of high-resolution 3D modeling of rupture

687   dynamics and seismic wave propagation accounting for the complexity of EGS environments and

688 constrained by few observational parameters shedding light on the dynamics of induced and

689 triggered earthquakes. More sophisticated 3D models, fully coupling dynamic earthquake rupture

690 and seismic wave propagation with co-seismic and quasi-static fluid effects, such as poroelasticity,

691 thermal pressurization, pore pressure diffusion, and considering the geometric complexity of

692 networks of fractures and non-planar faults, may allow in future to capture the full physical

693 complexity of nucleation and dynamics of induced earthquakes.

694   In the near future, such physics-based approaches may be synergistically integrated with

695 near-field seismic monitoring before, during, and after EGS operation, thus complementing traffic

696 light systems for hazard and risk mitigation (Bommer et al., 2006; Mignan et al., 2015).

697

Data and resources

699 All regional waveforms used in this study were downloaded from Incorporated Research

700 Institutions for Seismology (IRIS; https://www.iris.edu (last accessed February 2020)) data

701 management system using FDSN client. PREM anisotropic 2 s can be downloaded in the IRIS

702 data services products (http://ds.iris.edu/ds/products/syngine/ (last accessed February 2020)). All

703 parameters used for the preferred Model 2F are available at

704 (https://drive.google.com/open?id=1nm3HZ_YOD-j8t_YatTFfs9prVKplEExj). The

705 supplemental for this article provides additional figures, a table, and a movie mentioned in the

706 article.

1045

1046   **TABLES:**

1047   **Table 1**. *Fault friction parameters assumed in this study*

Parameter	Symbol	Value
Direct effect parameter	a	0.01 - 0.02 for z≤3.3 km and 0.01 for z > 3.3 km
Evolution effect parameter	b	0.014
Reference slip velocity	V_0	10^{-6}m/s
Steady-state friction coefficient at V_0	f_0	0.6
State-evolution distance	L	0.2 m
Weakening slip velocity	V_W	0.1 - 1.0 for z≤3.3 km and 0.1 for z > 3.3 km
Fully weakened friction coefficient	f_W	0.1
Initial slip rate	V_{ini}	10^{-16}m/s

1048

1049 **LIST OF FIGURE CAPTIONS:**

1050 **Figure 1.** Map of the South Korean Peninsula showing the near-regional broadband stations (blue

1051 triangles). Solid and dashed lines represent the Yangsan and interpreted geological faults near the

1052 Pohang EGS site, respectively. The two inset plots present the location and geometry of the faults

1053 of Model 1F (upper panel) and Model 2F (lower panel). The thicker black lines mark the near-

1054 surface edge of the fault planes. Colored dots depict aftershocks locations extracted from Kim et

1055 al. (2018). The non-double-couple solution of Grigoli et al. (2018) is also shown.

1056

1057 **Figure 2**. Fault reconstruction using guided anisotropic location uncertainty distribution (g-

1058 ACLUD). a) Spatiotemporal density plot of the mainshock and aftershocks based on the nearest-

1059 neighbor distance. b), c) and d) Two fault plane geometry inferred by the g-ACLUD method. The

1060 main fault plane has a strike of 214° and dips at 65°, while the secondary fault plane has a strike

1061 199° and dips at 60°. Black dots depict the seismicity used in this study. The geometry of the faults

1062 is shown in views b) as view from North, in c) as view from South, and d) in map view. The red

1063 star denotes the hypocenter of the Pohang earthquake.

1064

1065 **Figure 3**. 3D rendering of the unstructured tetrahedral computational mesh, and the fault plane

1066 with final slip on the 2 fault preferred model (Model 2F) of the Pohang earthquake (warm colors,

1067 in m), and the radiated seismic wavefield 5 seconds after rupture initiation (cold colors, absolute

1068 particle velocity in m/s). Note the strong effect of the high-resolution topography on modulating

1069 the seismic wavefield.

1070

1071 **Figure 4**. Graphical summary of the outcome of 180 dynamic rupture simulations assuming

1072 different combinations of initial relative prestress ratio (R_0), fluid-pressure ratio (γ) and direction

1073 of S_{Hmax}. The corresponding 180 square frames are filled with color if the combination of

1074 parameters is able to trigger self-sustained rupture beyond the nucleation region on any fault. The

1075 S_{Hmax} direction is indicated by the size of the frame, leading to six imbricated frames for each set

1076 of prestress and fluid-pressure ratio parameters.

1077

1078 **Figure 5**. Overview of the simulated earthquake rupture of the preferred model (Model 2F),

1079 showing in a) and b) the space-time evolutions of the absolute slip-rate (in m/s) across the main

1080 and secondary fault plane. a) (left panel) view from North displaying the main fault rupture.

1081 Snapshots every 0.1 s. (right panel) view from South highlighting the rupture of a portion of the

1082 secondary fault. Snapshots every 0.05 s. b-c) Rupture-time contours at intervals of 0.2 s.

1083

1084 **Figure 6**. Distribution of absolute fault slip (in m) in a) and b), and rake angles (in degrees) in c)

1085 and d) for the preferred dynamic rupture scenario (Model 2F) a) and c) view from North

1086 highlighting the main fault rupture. b) and d) view from South highlighting the rupture of a portion

1087 of the secondary fault. The white star in panel a) marks the considered hypocenter location.

1088

1089 **Figure 7**. Moment rate release of a) Model 1F and b) Model 2F and moment tensor

1090 representation of the preferred one-fault c) and two-fault d) models.

1091

1092 **Figure 8**. Comparison of synthetic and observed ground motion waveforms. a) Distribution of

1093 virtual stations (green triangles) at which synthetic waveforms are compared in b). The beachball

1094   is the moment tensor representation of the preferred 2 planes model scenario (Model 2F). Solid

1095   and dashed red lines represent the mapped Yangsan fault surface trace and the interpreted fault

1096   traces near the Pohang EGS site, respectively. The two rectangles show the location and geometry

1097   of the faults used in this study. b) Comparison of synthetic waveforms using one (Model 1F, blue

1098   dashed lines) and two fault planes (Model 2F, red solid lines) at the 19 dummy stations located in

1099   a). A 0.1 - 2 Hz 4th order Butterworth filter is applied to all traces. All traces are normalized. For

1100   each trace, the maximum velocity amplitude (in m/s) of Model 1F is indicated within a black

1101   square. c) Observed (black) and synthetic (red) waveforms for five regional stations for up-down

1102   (UD), east-west (EW) and north-south (NS) components (all located in South Korea, see blue

1103   triangles in Figure 1. t = 0 s denotes the origin time of the Pohang earthquake. A 0.033-0.08 Hz

1104 4th order Butterworth filter is applied to all traces. Synthetic regional waveforms are generated

1105   from the preferred dynamic rupture scenario Model 2F using Instaseis (Krischer et al., 2017) and

1106   2 s accurate Green's functions based on the PREM anisotropic model.

1107

1108   **Figure 9**. ((a) and (b)) Co-seismic surface displacements in the InSAR Line-of-sight (LoS)

1109   direction (in m) generated by a) Model 1F; one-plane (rectangle) and b) Model 2F; two-planes

1110   (two rectangles) preferred dynamic rupture scenario, respectively. The dashed red lines represent

1111   the traces of the interpreted faults near the EGS site.

1112

1113

1114   **FIGURES:**
1115

Figure 1. Map of the South Korean Peninsula showing the near-regional broadband stations (blue

triangles). Solid and dashed lines represent the Yangsan and interpreted geological faults near the

Pohang EGS site, respectively. The two inset plots present the location and geometry of the faults

of Model 1F (upper panel) and Model 2F (lower panel). The thicker black lines mark the near-

surface edge of the fault planes. Colored dots depict aftershocks locations extracted from Kim et

al. (2018). The non-double-couple solution of Grigoli et al. (2018) is also shown.

1124

Figure 2. Fault reconstruction using guided anisotropic location uncertainty distribution (g-ACLUD). a) Spatiotemporal density plot of the mainshock and aftershocks based on the nearest-neighbor distance. b), c) and d) Two fault plane geometry inferred by the g-ACLUD method. The main fault plane has a strike of 214° and dips at 65°, while the secondary fault plane has a strike 199° and dips at 60°. Black dots depict the seismicity used in this study. The geometry of the faults is shown in views b) as view from North, in c) as view from South, and d) in map view. The red star denotes the hypocenter of the Pohang earthquake.

1132

Figure 3. 3D rendering of the unstructured tetrahedral computational mesh, and the fault plane with final slip on the 2-fault preferred model (Model 2F) of the Pohang earthquake (warm colors, in m), and the radiated seismic wavefield 5 seconds after rupture initiation (cold colors, absolute particle velocity in m/s). Note the strong effect of the high-resolution topography on modulating the seismic wavefield.

Figure 4. Graphical summary of the outcome of 180 dynamic rupture simulations assuming different combinations of initial relative prestress ratio (R_0), fluid-pressure ratio (γ) and direction of S_{Hmax}. The corresponding 180 square frames are filled with color if the combination of parameters is able to trigger self-sustained rupture beyond the nucleation region on any fault. The S_{Hmax} direction is indicated by the size of the frame, leading to six imbricated frames for each set of prestress and fluid-pressure ratio parameters.

Figure 5. Overview of the simulated earthquake rupture of the preferred model (Model 2F), showing in a) and b) the space-time evolutions of the absolute slip-rate (in m/s) across the main and secondary fault plane. a) (left panel) view from North displaying the main fault rupture.

1155   Snapshots every 0.1 s. (right panel) view from South highlighting the rupture of a portion of the

1156   secondary fault. Snapshots every 0.05 s. b-c) Rupture-time contours at intervals of 0.2 s.

1193 the traces of the interpreted faults near the EGS site.

1194

1195 **APPENDIX**

1196 **A1 Friction parameters**

1197 To parameterize the frictional behavior, we use laboratory-based rapid velocity weakening friction

1198 law proposed by the community benchmark problem TPV104 Southern California Earthquake

1199 Center (SCEC-benchmark) (Harris et al., 2018). The friction law is adapted from - the formulation

1200 introduced by Dunham et al. (2011a). The governing equations in our notation are described in

1201 Ulrich et al. (2019a), the implementation in SeisSol is described and verified in Pelties et al. (2014).

1202 Figure S1b shows the depth-dependent direct effect a and weakening slip velocity V_W. The

1203 evolution effect parameter b is set constant. We apply a velocity strengthening zone at the top 200

1204 m of all faults to smoothly stop rupture. Within this zone, values for a and V_W increase linearly

1205 ranging from 0.01 and 0.1 m/s below depth of 3.3 km to 0.02 and 1.0 m/s to the surface,

1206 respectively. Table 1 lists all friction parameters used in this study.

1207

1208 **Table 1**. *Fault friction parameters assumed in this study*

Parameter	Symbol	Value
Direct effect parameter	a	0.01 - 0.02 z≤3.3 km and 0.01 z > 3.3 km

Evolution effect parameter	b	0.014
Reference slip velocity	V_0	10^{-6}m/s
Steady-state friction coefficient at V_0	f_0	0.6
State-evolution distance	L	0.2 m
Weakening slip velocity	V_W	0.1 - 1.0 z≤3.3 km and 0.1 z > 3.3 km
Fully weakened friction coefficient	f_W	0.1
Initial slip rate	V_{ini}	10^{-16}m/s

1209

A2 Nucleation procedure

1210

1211 To nucleate the earthquake, we apply a time-dependent overstress centered at the hypocenter

1212 location, that is at longitude and latitude of 129.37° and 36.11°, respectively, and at a depth of 4.27

1213 km. The time-dependent overstressed nucleation area $R_{nuc}(t)$ is determined by increasing the

1214 initial relative prestress ratio R_0 as:

1215

1216 $$R_{nuc}(t) = R_0 + \Omega(r) \times S(t) \tag{A2.1}$$

1217

1218 where $\Omega(r)$ is a Gaussian-step function, r is the radius from the hypocenter, and $S(t)$ denotes the

1219 smoothed step function. The Gaussian-step function is defined as:

1220

1221 $$\Omega(r) = \xi \, exp(\frac{r^2}{r^2 - r_c{}^2}) \quad \text{for } r < r_c \; ; \qquad \Omega(r) = 0 \quad \text{otherwise} \qquad \text{(A2.2)}$$

1222

1223 where ξ is the overstressed initial relative prestress ratio and $r_c = 500$m is the radius of the

1224 nucleation patch. We only overstress the main fault plane; In the nucleation region, we set ξ to 2,

1225 and apply an overstress characterized by $S_{Hmax}= 77°$ and $v = 0.1$. These values are set by trial-

1226 and-error to allow rupture to propagate spontaneously with the least magnitude of overstress and

1227 to limit fault slip inside the nucleation patch. The orientation of S_{Hmax} is also in accordance with

1228 Korean Government Commission, 2019 and Ellsworth et al. (2019) which suggest optimally

1229 oriented stress orientation and critically stressed inside the nucleation zone. The smoothed step

1230 function is formulated as:

1231

1232 $$S(t) = exp(\frac{(t-T)^2}{t \times (t - 2 \times T)}) \quad \text{for } 0 < t < T; S(t) = 1 \quad \text{for } t \geq T \qquad \text{(A2.3)}$$

1233

1234 where $T = 0.4$s is the nucleation time.

1235

1236 ## A3 Methodology

1237 **A3.1 Numerical method**

1238 We use the open-source software SeisSol (Dumbser and Käser, 2006; Pelties et al., 2014; Uphoff

1239 et al., 2017; Wollherr et al., 2018) (https://github.com/SeisSol/SeisSol), which couples seismic

1240 wave propagation in complex media and frictional fault failure. SeisSol uses an Arbitrary high-

1241 order DERivative-Discontinuous Galerkin (ADER-DG) approach which achieves high-order

1242 accuracy in space and time (Käser and Dumbser, 2006). SeisSol uses flexible non-uniform

1243 unstructured tetrahedral mesh, which allows accounting for complex geometric features such as

1244 3D fault networks or high-resolution topography across a large range of scales: from small-scale

1245 fault roughness, large-scale fault structures to fault-to-fault interaction. Dynamic rupture

1246 simulations are sensitive to geometrically complexity of faults (Dunham et al., 2011b; Shi and

1247 Day, 2013; Uphoff et al., 2017; Wollherr et al., 2018, 2019; Ulrich et al., 2019a, 2019b).

1248   A high resolution and accurate simulation are essential to resolve the detailed processes of

1249 rupture propagation of the intersected fault geometry. We motivate the presented deterministic

1250 parameter study with the computational feasibility of many such simulations. While the feasibility

1251 of dynamic rupture inversion and statistical learning approaches has been demonstrated (e.g.

1252 Peyrat et al. 2001; Bauer et al., 2018, Happ et al. 2019, Gallovič et al. 2019a, Gallovič et al. 2019b),

1253 these are restricted by near-field data availability and the computational cost of each forward

1254 dynamic rupture model.

1255   SeisSol is verified in a wide range of benchmark problems, including dipping faults,

1256 branched and curved faults, on-fault heterogeneity, and laboratory-based friction laws (de la

1257 Puente et al., 2009; Pelties et al., 2012; Pelties et al., 2014; Wollherr et al., 2018,) in line with the

1258 SCEC-Benchmark Dynamic Rupture code verification exercises (Harris et al., 2011; Harris et al.,

1259 2018) as well as against analytical reference solutions for seismic wave propagation (e.g., Uphoff

1260 and Bader, 2016; Wolf et al., 2020). Fast time to solution is achieved thanks to end-to-end

1261 optimization (Breuer et al., 2014; Heinecke et al., 2014; Rettenberger et al., 2016), including an

1262 efficient local time-stepping algorithm (Breuer et al., 2016, Uphoff et al., 2017). This efficient

1263 algorithm on high-performance computing architecture provides up to ten-fold speed up (Uphoff

1264 et al., 2017).

1265   SeisSol allows accounting for off-fault yielding. Inelastic energy dissipation influences

1266   rupture dynamics such as rupture speed and rupture style (e.g., Gabriel et al., 2013). Off-fault

1267   plasticity is incorporated using the off-line code generator to compute matrix operations in an

1268   efficient way (Wollherr et al., 2018). SeisSol also supports visco-elastic rheologies, using an off-

1269   line code generator similar to that off-fault plasticity. In this study, we use a spatiotemporal

1270   discretization of polynomial degree $p = 4\ (O5)$ for all simulations.

1271

1272   **A3.2 Mesh generation**

1273   The simulation domain and fault plane geometry model are created using third-party software

1274   GoCad (Emerson paradigm holding, 2018) in a Cartesian coordinate system. We discretize the

1275   unstructured tetrahedral mesh using the meshing software Simmodeler (Simmetrix Inc., 2017).

1276   The mesh element edge length size to 50 m close to the fault plane and 200 m at the surface

1277   topography, yielding a 4 million volume cell mesh. The mesh size on the fault plane is examined

1278   prior to the simulation by calculating the cohesive zone (or process zone) to ensure convergence.

1279   Wollherr et al. (2018, 2019) provide a way to resolve the cohesive zone for the case of SeisSol. To

1280   save the computational costs and at the same time avoid reflection from the domain boundary, we

1281   gradually increase the edge length size of the tetrahedral element by a factor of 6% away from the

1282   fault plane and surface topography. Figure 3 depicts the unstructured tetrahedral mesh used in this

1283   study, overlain by a snapshot of the absolute velocity field at simulation time 5 s, for our preferred

1284   dynamic rupture model (Model 2F), highlighting the effect of the topography on the near-field

1285   ground motions.

1286   The locally refined mesh and high-order spatiotemporal discretization allow capturing the

1287   high-frequency content of the waveforms with high accuracy (little numerical dispersion),

1288   especially in the near-fault region. We estimate the maximum resolved frequency is up to 4 Hz

1289   within 7 km distance from the fault zone, and around 1 Hz at 30 km distance from the fault.

1290   Simulating 5 s typically requires 15 minutes (average run-time) on Intel Haswell cores with 128

1291   nodes using supercomputer Cray XC40 Shaheen-II, King Abdullah University of Science and

1292   Technology, Saudi Arabia.
