### Key Points:

- We present a new coral proxy system model to facilitate comparison between proxy observations and climate model output
- Analytical and calibration errors, variable growth rates, and age modeling uncertainties all have measurable impacts on interannual variance
- The relative importance of different uncertainties on interannual variance are site-dependent

### 1 Abstract

2 Coral records of surface-ocean conditions extend our knowledge of interannual El Niño-Southern 3 Oscillation (ENSO) variability into the pre-instrumental period. That said, internal variability within the climate system as well as multiple sources of uncertainties inherent to the coral archive produce 4 5 challenges for the paleoclimate community to detect forced changes in ENSO using coral 6 geochemical records. We present a new coral proxy system model (PSM) of intermediate complexity, geared toward the evaluation of changes in interannual variance. Our coral PSM adds additional layers 7 8 of complexity to previously published transfer functions that describe how the archive responds to 9 sea-surface temperature (SST) and salinity. We use SST and salinity output from the Community 10 Earth System Model Last Millennium Ensemble 850 control to forward-model coral oxygen isotopic ratios and SST derived from Sr/Ca. We present a detailed analysis of our coral PSM using climate 11 12 model output for sites in the central and southwest Pacific before subsequently extending the analyses to span the broader tropical Pacific. We demonstrate how analytical and calibration errors, variable 13 growth rates, and age model assumptions systematically change interannual variance, and show that 14 the relative magnitude of the variance change is location dependent. Importantly, however, we find 15 16 that even with the added uncertainties in our PSM, corals spanning the circum-Pacific are broadly able to capture decadal and longer (decadal+) changes in ENSO variability. Our code is publicly 17 18 available to the broader community and documented on GitHub to facilitate future comparisons between model output and coral proxy data.

19 20

## 21 Plain Language Summary

Climate scientists use the chemistry of coral skeletons to study past tropical climate conditions.
 Specifically, the elemental ratio of strontium to calcium (Sr/Ca) and the oxygen isotopic composition

 $(\delta^{18}\text{O})$  in the coral skeleton have demonstrated utility. Coral Sr/Ca varies in response to changes in sea-surface temperature, whereas coral  $\delta^{18}\text{O}$  records both changes in temperature and salinity.

Individual corals provide tens to hundreds of years of climate information from the tropical oceans.

They are well-suited for studying variability related to the El Niño-Southern Oscillation (ENSO), aclimate phenomenon that impacts global temperature and rainfall patterns every few years. We rely

29 on both climate proxy data and simulations from global climate models to study changes in ENSO

variability in the past. Nevertheless, it is difficult to directly compare proxy data with climate model

output due to the imperfect nature of how the climate signal is recorded in the coral skeleton. Proxy system models are a tool designed to help bridge the gap between climate information recorded in

32 system models are a tool designed to help bridge the gap between climate information recorded in 33 corals and climate model output. In this study, we develop a coral proxy system model to demonstrate

how different processes impact a coral's ability to record changes in ENSO variability.

35

### 36 1 Introduction

Geochemical records from massive corals provide decades to centuries of sub-annually resolved proxy climate data from the tropical oceans [*Fairbanks et al.*, 1997; *Gagan et al.*, 2000; *Lough*, 2010]. The ratio of strontium to calcium (Sr/Ca) and the oxygen isotopic composition ( $\delta^{18}$ O) of coral skeletal material are established climate proxies [*Fairbanks et al.*, 1997; *Corrège*, 2006; *Lough*, 2010; *DeLong* 

40 Inactual are established enhalter proxies [*Putrbunks et al.*, 1997, Correge, 2000, *Lough*, 2010, *Delong* 41 *et al.*, 2013]. Sea-surface temperature (SST) exerts the dominant climate control on coral Sr/Ca

42 [Weber, 1973; Smith et al., 1979; Beck et al., 1992], whereas coral  $\delta^{18}$ O is jointly influenced by SST

43 and the oxygen isotopic composition of seawater ( $\delta^{18}O_{sw}$ ) [Weber and Woodhead, 1972; Gagan et

44 *al.*, 1998; *Ren et al.*, 2003], the latter of which is impacted by similar processes as sea-surface salinity

45 (e.g., rainfall, evaporation, advection of different water masses, and freshwater runoff) [*LeGrande* 

46 and Schmidt, 2006]. Geochemical records from tropical Pacific corals provide insight into El Niño-

Southern Oscillation (ENSO) variability, the leading mode of interannual climate variability with 47 global impacts on temperature and precipitation patterns [Bjerknes, 1969; Ropelewski and Halpert, 48 49 1987].

50

51 SST anomalies (SSTA) averaged across the Niño 3.4 region in the central equatorial Pacific (5°N-52 5°S, 120-170°W), shows an increase in the magnitude and frequency of extreme ENSO events over 53 the last few decades [Trenberth and Hoar, 1996; Bin Wang et al., 2019]. However, instrumental observations are of insufficient length [Fairbanks et al., 1997; Deser et al., 2010] to characterize the 54 full range of internal variability [Wittenberg, 2009]. Model simulations of future ENSO changes differ 55 widely in response to both external forcing of increasing greenhouse gas emissions and internal 56 variability in the climate system [Collins et al., 2010; DiNezio et al., 2013; Bellenger et al., 2014; Cai 57 58 et al., 2014; 2015]. Coral-based climate records that overlap with, and extend beyond, the instrumental period provide tests of climate model simulations of ENSO [Gagan et al., 2000; Cobb 59 60 et al., 2013; Schmidt et al., 2014].

61

62 There are, however, several sources of uncertainty that impact our ability to understand past changes 63 in ENSO variability, including those due to the climate system and from the coral archive. ENSO behavior can vary in the absence of forcings external to the climate system [Wittenberg, 2009; Deser 64 65 et al., 2012], making it difficult to separate internally versus externally driven changes in variability 66 from short (several decades or less) coral records. There also needs to be a clear link between variability at the individual reef site and ENSO. Lastly, the coral archive itself impacts how a climate 67 signal is recorded. These sources of uncertainty are summarized as follows: 68 69

- 1. The ability of a point-source location to capture regional changes in ENSO variability 70
  - 2. Internal variability of the climate system
  - 3. The ability of coral Sr/Ca and  $\delta^{18}$ O to record ocean-climate variables
  - 4. Uncertainties in the coral archive that may obfuscate the climate signal of interest (e.g., variable growth rates)
- 73 74

71

72

- 5. Proxy observation uncertainties (e.g., analytical, calibration, dating, and age-model errors)
- 75

A proxy system model (PSM) addresses some of these challenges and serves as an important bridge 76 between proxy data and observations or model output [Evans et al., 2013; Dee et al., 2015], as one 77 78 can mathematically model how different processes impact a climate signal that emerges from the 79 proxy data. Typically, paleoclimate proxy data is transformed back into a climate variable (e.g., SST) 80 using empirically determined calibration equations [Corrège, 2006]. Conversely, forward modeling via a PSM transforms observations or climate model output into "pseudoproxies" that estimate the 81 82 proxy signal [Evans et al., 2013; Dee et al., 2015].

83

84 In this study, we use surface temperature and salinity output from the Community Earth System Model Last Millennium Ensemble (CESM-LME) to forward model "pseudocoral" [Brown et al., 85 86 2008]  $\delta^{18}$ O and SST derived from Sr/Ca (SST<sub>Sr/Ca</sub>). We first focus on the central (Christmas Island) and southwest Pacific (Vanuatu) to demonstrate the subcomponents of our PSM, and then expand our 87 88 pseudoproxy network to span the tropical Pacific. Our coral PSM adds layers of complexity to the transfer functions that describe how the archive responds to SST and salinity [Thompson et al., 2011; 89 90 Dee et al., 2015]. We identify how uncertainties associated with 1) analytical and calibration errors, 91 2) variable growth rates, and 3) age modeling assumptions, impact interannual variance and the ability 92 of a pseudocoral to capture decadal and longer (decadal+) changes in ENSO variability. Although precise month-to-month SST variations in the Niño 3.4 region are a common target for ENSO studies, 93

this is challenging for paleoclimate studies because of temporal uncertainties in proxy records [Emile-94

95 Geay et al., 2013a; 2013b]. Thus, we focus on how various coral processes impact estimates of

96 decadal+ changes in ENSO variability in coral paleoclimate reconstructions. Sections 2 and 3 describe

97 the coral PSM framework. Coral archive uncertainties on interannual variance as well as a coral's

ability to capture changes in ENSO variability are presented in section 4. Conclusions are providedin section 5.

## 101 2 Coral PSM Framework

Proxy system models are tools used to evaluate the contribution of local environmental signals and their variability on the measured proxy record. Coral PSMs have previously been used to make more advanced comparisons between observations and climate model data [*Thompson et al.*, 2011], quantify uncertainties in signal interpretation [*Dee et al.*, 2015], and quantify errors in coral-based ENSO amplitude [*Russon et al.*, 2015] or variability estimates [*Stevenson et al.*, 2013]. Here, we introduce a coral PSM that builds upon previous work and adds new layers of complexity by incorporating uncertainties related to:

- 109 1. Variable growth rates experienced when sampling a coral along the maximum growth axis
  - 2. Analytical and calibration errors
  - 3. Seasonal chronological uncertainties associated with transforming coral geochemical data from the depth to the time domain (herein referred to as the age model)

114 Our design adheres to the PSM framework described in Evans et al. [2013] where a PSM consists of environment, sensor, archive, and observation subcomponents (Figure 1). This is the first study that 115 116 includes an archive-based coral PSM with a variable growth rate algorithm. Analytical and calibration errors as well as the age model assumptions fall within the observation PSM. Our coral PSM is 117 optimized to use Monte Carlo methods to run any permutation of the various archive and observation 118 sub-models (Figure 1 arrows) and generate *n* realizations of pseudocoral  $\delta^{18}$ O or SST<sub>Sr/Ca</sub>. This study 119 120 focuses on how various uncertainties impact interannual variance, a leading timescale of interest for 121 coral-based paleoclimatology.

122 Figure 1. Coral proxy system model (PSM) schematic. The sea-123 surface temperature (SST), sea-surface salinity (SSS), or the oxygen 124 isotopic composition of sea water ( $\delta^{18}O_{sw}$ ) environmental inputs 125 (green box) can come from instrumental observations, climate model 126 output, or reanalysis data [Evans et al., 2013; Dee et al., 2015]. Here 127 and in all subsequent figures, SST<sub>Sr/Ca</sub> refers to SST derived from 128 coral Sr/Ca. The coral  $\delta^{18}$ O sensor model [*Thompson et al.*, 2011] 129 accounts for sensitivity to SST and  $\delta^{18}O_{sw}$  (SSS). The growth rate 130 archive model (purple box) describes how an environmental signal 131 may be emplaced or transformed in the coral archive due to variable 132 growth rates. The coral observation models (blue boxes) include the 133 combined effect of analytical and calibration errors, as well as age 134 model uncertainties that arise from transforming the coral 135 geochemical from the depth to the time domain. Arrows shows 136 possible permutations of the archive and observation sub-models to 137 vield pseudocoral output. The full coral PSM refers to consecutively 138 perturbing the environmental inputs with the growth rate, 139 analytical/calibration, and age-model algorithms.

### 140 2.1 Coral PSM Input Variables

141 The environmental inputs for the coral PSM are SST, sea-surface salinity (SSS), and  $\delta^{18}O_{sw}$  if 142 available (Figure 1). These climate variables can be from instrumental observations or model output. 143 Here we use surface temperature and salinity output from the CESM-LME 850 control as the

environmental inputs [Otto-Bliesner et al., 2016]. The CESM-LME uses version 1.1 of CESM with 144 the Community Atmospheric Model Version 5, CESM1(CAM5) [Hurrell et al., 2013]. The CESM-145 LME uses  $\sim 2^{\circ}$  resolution for the atmosphere and  $\sim 1^{\circ}$  resolution for the ocean. Surface salinity data 146 (0-10 m depth) was gridded to the same  $\sim 2^{\circ}$  resolution as the atmospheric components to facilitate 147 forward modeling coral  $\delta^{18}$ O as a linear combination of SST and SSS. There are no changes in 148 external forcing throughout the 850 control simulation [Otto-Bliesner et al., 2016], hence all 149 150 variability is internal. The long control allows us to sample across a wide range of internal variability. which is not possible in the short instrumental record, and to quantify how different assumptions and 151 uncertainties inherent to the coral archive impact interannual variance in a geochemical time series. 152

153

154 Herein we seek to understand how different coral uncertainties impact interannual variance within the CESM-LME depiction of climate. We thus evaluate the proxy uncertainties within the simulated 155 climate generated by the model, such that we constrain ourselves to the CESM-LME's simulation of 156 tropical Pacific variability, including ENSO. The spatial patterns observed using the CESM-LME 157 may not be strictly comparable to other models, but the general results about how the three coral 158 uncertainties impact interannual variability are broadly applicable to environmental inputs from 159 observations or other climate models. Due to model biases, we caution users of the PSM to avoid 160 161 direct point-to-point comparisons between coral observations and climate model output from a single grid point. Care must be taken to select a broader region that best matches the climate conditions 162 observed at the proxy site. 163

164

#### 165 2.2. Coral Sensor Models

2.2.1 Pseudocoral  $\delta^{18}O$ 166

167 We use the sensor model of *Thompson et al.* [2011] to forward model mean-removed pseudocoral  $\delta^{18}$ O anomalies ( $\Delta\delta^{18}O_{\text{pseudocoral}}$ ) as a linear combination of SST and  $\delta^{18}O_{\text{sw}}$  or salinity anomalies: 168  $\Delta \delta^{18} O_{\text{pseudocoral}} = a_1 \Delta \text{SST} + \Delta \delta^{18} O_{\text{sw}}$  (Eq. 1)

- 169
- 170
- 171

The coefficient  $a_1$  is based on the inverse SST dependence that arises from thermodynamic 172 173 fractionation [Epstein et al., 1953]. We use a slope -0.22 ‰/°C for a<sub>1</sub> as used in Thompson et al. 174 [2011], but recognize that other slope values exist in the literature [Evans et al., 2000].

 $\Delta \delta^{18} O_{\text{pseudocoral}} = a_1 \Delta \text{SST} + a_2 \Delta \text{SSS}$  (Eq. 2)

175

176 SSS and  $\delta^{18}O_{sw}$  are often assumed to be linearly proportional as they are impacted by similar precipitation, evaporation, and advection processes [LeGrande and Schmidt, 2006]. We use Eq. 2 and 177 approximate  $a_2$  using observed  $\delta^{18}O_{sw}$ -SSS slopes determined from basin-scale regression analysis 178 [LeGrande and Schmidt, 2006]. Limited  $\delta^{18}O_{sw}$  and SSS observations [LeGrande and Schmidt, 2006], 179 spatiotemporal variability in the  $\delta^{18}O_{sw}$ -SSS relationship [Conroy et al., 2017], or sub-grid processes 180 affecting  $\delta^{18}O_{sw}$  [Stevenson et al., 2015] can lead to large errors on interannual variance [Stevenson 181 et al., 2013; Russon et al., 2015] and hinder direct comparison between forward modeled 182 183 pseudocorals and coral proxy observations. Since our study focuses on the impact of other processes on interannual variance we define  $a_2$  as 0.27 for the tropical Pacific and 0.45 for the South Pacific as 184 in Legrande & Schmidt [2006]. 185

186

#### 2.2.2 Pseudocoral SST Derived from Sr/Ca (SST<sub>Sr/Ca</sub>) 187

188 The inverse relationship between coral Sr/Ca and temperature is an established proxy for reconstructing SST variability [Beck et al., 1992; Gagan et al., 2000; Quinn and Sampson, 2002; 189

190 *Corrège*, 2006; *Lough*, 2010]. Slope values for Sr/Ca-SST typically fall within the  $-0.06 \pm 0.01 (\pm 1\sigma)$ mmol/mol/°C range for the Indo-Pacific [Corrège, 2006]. Uncertainties in the Sr/Ca-SST calibration 191 192 can yield errors in the SST reconstruction up to  $0.35^{\circ}C (\pm 2\sigma)$  [*Ouinn and Sampson*, 2002], although 193 this uncertainty may be higher based on interlaboratory comparisons [Hathorne et al., 2013] and 194 reproducibility studies [Sayani et al., 2019]. In this study we assume that the original SST input to 195 the coral PSM is a reasonable approximation of SST derived from coral Sr/Ca (SST<sub>Sr/Ca</sub>). A published 196 coral Sr/Ca sensor model does not exist at the time of this study but could be incorporated into our 197 coral PSM framework in the future.

198

## 199 2.3 Pseudocoral Case Studies: Christmas Island & Vanuatu

200 ENSO involves basin-scale atmospheric and oceanic interactions across the tropical Pacific, with the largest interannual signal occurring in the central and eastern equatorial Pacific. In contrast, coral 201 heads are from point-source locations (on the scale of meters) that are impacted by both regional and 202 203 local climate processes. Thus, there needs to be a demonstrated link between climate variability at the 204 individual reef site and ENSO. Modern and paleo-ENSO studies have targeted sites within the Niño 3.4 region [Cobb et al., 2013; Emile-Geay et al., 2016], as well as sites in the eastern, western, and 205 206 southwest Pacific that are sensitive to changes in ENSO variability [Hereid et al., 2013a]. For 207 example, the western and southwest Pacific contain a large number of islands that are home to 208 abundant modern and fossil coral heads for paleoclimate studies [Cole et al., 1993; Kilbourne et al., 2004; Linsley et al., 2006; DeLong et al., 2012; Gorman et al., 2012; Hereid et al., 2013b; Jimenez 209 210 et al., 2018; and many others].

211

We choose two end-member localities (Christmas (Kirimati) Island (2°N, 157°W); Vanuatu (16°S, 167°E) to apply our coral PSM for testing how different processes and uncertainties inherent to coralbased paleoclimatology impact interannual variance. Christmas Island, located in the central equatorial Pacific, has a small annual cycle and a large interannual response, whereas Vanuatu, located within the SPCZ, has a larger annual cycle and a smaller interannual response. In all instances, when selecting the SST or forward modeled  $\Delta \delta^{18}O_{pseudocoral}$  (Eq. 2) input for the coral PSM, we use the model output from the grid point closest to the selected sites.

219

## 220 3. New PSM Design Following Laboratory and Analytical Practices for Coral Measurements

The full coral PSM refers to consecutively perturbing the original environmental inputs with variable
 growth rates, analytical and calibration errors, and the age modeling algorithm (Figure 1). The
 following subsections describe each subcomponent of the PSM.

224

### 225 *3.1 Variation in Coral Growth Rates*

226 Sub-seasonal resolution is a goal of many coral paleoclimate studies. However, a coral's growth rate 227 may vary both within and between years. For example, a *Porites* coral growing an average of 1.2 228 cm/year would achieve approximately monthly resolution if sampled in 1 mm increments. Although 229 monthly resolution is targeted, one sample of coral powder may average 2-3 weeks  $(-2\sigma)$  of time when the coral is growing faster, or 5-6 weeks  $(+2\sigma)$  when the coral is growing slower. Due to variable 230 231 growth rates, the net effect of equal sampling in the depth domain will lead to unequal sampling in the time domain. We use our coral PSM to assess how variations in coral growth impact the variance 232 233 of a resulting geochemical time series.

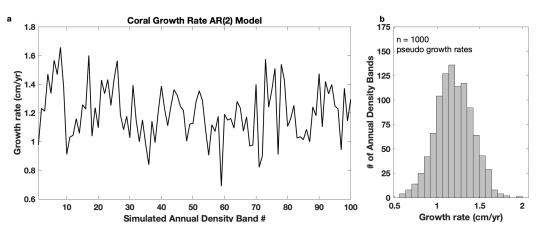

234

We measured the annual growth rates of 9 modern and fossil Porites cores from the southwest Pacific 235 to generate a distribution of growth rates with a mean of  $1.2 \pm 0.2$  cm/year ( $\pm 1\sigma$ ). The measured 236 237 growth rate values are consistent with the reported average values for *Porites* corals from other regions of the Pacific [Cobb et al., 2013]. We incorporate variable growth rates into the coral PSM 238 using an autoregressive order 2, AR(2), model since the measured annual growth rates are serially 239 correlated and cannot be modeled with an independent error term. The lag 1 and 2 correlation 240 coefficients (0.25 and 0.20, respectively), and the standard deviation (0.2 cm/year) for the AR(2) 241 242 model are based on measured *Porites* corals. The AR(2) model is used to generate a series of growth rates (Figure 2a). The distribution of simulated growth rates (Figure 2b) is consistent with the 243 measured coral growth rates. The parameters for the AR(2) model can easily be adjusted for different 244 245 species.

246

A realization of the AR(2) model provides a transformation from the time to the depth domain. One random realization for SST and forward modeled  $\Delta \delta^{18}O_{pseudocoral}$  is provided at Christmas Island and Vanuatu as an illustrative example of how the algorithm works (Figure 3a-d). The net effect of the variable growth rate algorithm is that the pseudocoral output looks stretched and compressed relative to the original input. Monte Carlo methods are employed to generate many random realizations.

252

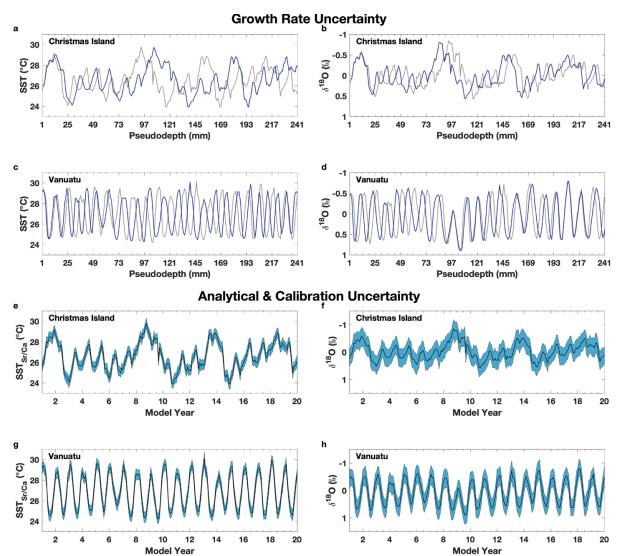

253 254

**Figure 2.** Simulated annual coral growth rates (cm/year). (a) A randomly generated realization of simulated growth rates for 100 pseudocoral annual density bands. The growth rates are simulated using an autoregressive order 2, AR(2), model with lag coefficients and variance parameters determined from measured *Porites* corals from the southwest Pacific (Section 3.1). Here we show one randomly generated realization of the AR(2) simulated growth rates, but note that the model can be run for *n* realizations. (b) Histogram of modeled pseudo "*Porites*" annual growth rates ( $1.2 \pm 0.2$  cm/year,  $\pm 1\sigma$ ). The pseudocoral annual growth rates are used stretch and compress the environmental inputs to mimic how equal sampling in the depth domain can yield to unequal sampling in the time domain.

### 263 3.2 Analytical and Calibration Errors

264 Monte Carlo methods are also used to randomly generate  $1000 \Delta \delta^{18}$ Opseudocoral and SST<sub>Sr/Ca</sub> time series perturbed with analytical and calibration errors modeled as Gaussian white noise (Figure 3e-h). For 265  $\Delta \delta^{18}O_{\text{pseudocoral}}$ , analytical errors are taken as 0.20% ( $\pm 2\sigma$ ), a value typical of laboratory analytical 266 precision. For coral SST<sub>Sr/Ca</sub>, we incorporate the combined effect of the analytical instrument error, 267 as well as the linear calibration error associated with transforming coral Sr/Ca into SST. Previous 268 work identified that the net effect of analytical and calibration errors can cause uncertainties of 269 270 ~0.30°C (±2σ) [Alibert and McCulloch, 1997; Schrag, 1999; Quinn and Sampson, 2002]. The original 271 SST environmental inputs are thus perturbed with Gaussian white noise that includes the combined impact of analytical and calibration errors (0.30°C,  $\pm 2\sigma$ ). The error term for SST<sub>Sr/Ca</sub> can be changed 272

273 within the PSM framework to account for larger analytical and calibration error terms that have been 274 previously reported [Corrège, 2006; DeLong et al., 2013; Hathorne et al., 2013; Savani et al., 2019]. 275

276 277

Figure 3. Impact of variable growth rates and analytical and calibration errors on environmental signals. (a-d) Blue curves 278 depicts the original SST (a, c) and  $\Delta \delta^{18}$ O<sub>pseudocoral</sub> (b, d) inputs transformed from the time to the depth domain using a 279 realization of the AR(2) variable growth rate model. Gray curves indicate the original inputs transformed to the depth 280 domain using a constant transformation of 1.2 cm/year (i.e., no variable growth rates) for the model grid points closest to 281 Christmas Island (a, b) and Vanuatu (c, d). Model output in this and all subsequent figures are from the CESM-LME 850 282 control [Otto-Bliesner et al., 2016] (Section 2.1).  $\Delta \delta^{18}$ Opseudocoral in this and all subsequent figures is generated using the 283 sensor model of *Thompson et al.* [2011] (Section 2.2.1). (e, g) Pseudocoral SST<sub>Sr/Ca</sub> perturbed with the combined effect 284 of analytical and calibration errors ( $\pm 0.30^{\circ}$ C,  $2\sigma$ ; Section 3.2) at the model grid points closest to Christmas Island (e) and 285 Vanuatu (g). (f, h)  $\Delta \delta^{18}O_{\text{pseudocoral}}$  perturbed with analytical error (±0.20‰, 2 $\sigma$ ; Section 3.2) for Christmas Island (f) and 286 Vanuatu (h). Black line in (e-h) indicates the unperturbed environmental inputs for the selected sites, and the blue shading 287 represents the spread of forward modeled pseudocoral time series (n = 1000). For clarity, each panel includes a 20-year 288 subset of the 850 control to show how variable growth rates and analytical/calibration errors impact the original inputs.

#### 289

#### 290 3.3 Monthly Coral Chronology

291 The creation of an age model in coral paleoclimate studies often requires the measured climate indicator (proxy) be transformed from the depth into the time domain. We investigate the impact of 292

8

key age modeling assumptions on interannual variance. We note that the assumptions discussed here are different than the uncertainties that arise from missing or double counting years in annually banded archives [*Comboul et al.*, 2014] that have been previously incorporated into existing PSM frameworks [*Dee et al.*, 2015].

297

298 The chronology for approximately monthly-resolved coral data typically uses annual cyclicity in the 299 data and the summer and wintertime extremes to constrain a relative chronology. For coral Sr/Ca, larger values indicate cooler temperatures, while smaller values indicate warmer temperatures 300 [Weber, 1973; Smith et al., 1979; Beck et al., 1992]. For coral  $\delta^{18}$ O, more negative extrema indicate 301 warmer and/or fresher conditions often experienced during the summer, while more positive extrema 302 indicate cooler and/or more saline conditions experienced during the winter [Fairbanks et al., 1997; 303 304 Corrège, 2006; Lough, 2010]. Peaks and troughs identified in the geochemical data are assigned a calendar month based on knowledge about the climatology at a given site, and then the data is 305 306 interpolated to achieve monthly resolution. The relative age model can be further refined by overlapping the coral record with instrumental observations (modern corals only) and with high-307 precision <sup>230</sup>Th ages that serve as absolute chronological constraints with errors ~1% of the age [Shen 308 et al., 2012; Cheng et al., 2013]. 309

310

311 We developed a publicly available MATLAB® algorithm to standardize coral age modeling. The 312 age-model algorithm assumes optimal sampling [DeLong et al., 2013] of the coral at sub-seasonal resolution. Input variables include the estimated sampling resolution (e.g., 10-14 samples per annual 313 314 growth band), the target temporal resolution (defaults to 12 points/year), and the climatological 315 warmest and coldest months at a given location. The climatological warmest/coldest month assignment can be determined from instrumental observations or model output for past time intervals 316 317 when the annual cycle is not known. The algorithm identifies peaks and troughs in the geochemical 318 data that are then assigned a particular calendar month based on the climatological input. The 319 algorithm also contains an option to constrain the number of years based on an approximate number 320 of annual density bands visible in a coral's X-ray image. The number of years constraint is often not 321 necessary for sites with a clear annual cycle (e.g., the southwest Pacific), but may be necessary for sites with a small and/or noisy annual cycle (e.g., the equatorial Pacific). Once an optimal number of 322 peaks/troughs are iteratively identified, the geochemical data is interpolated to the target resolution 323 324 using a piecewise linear transformation [Fritsch et al., 1980].

325

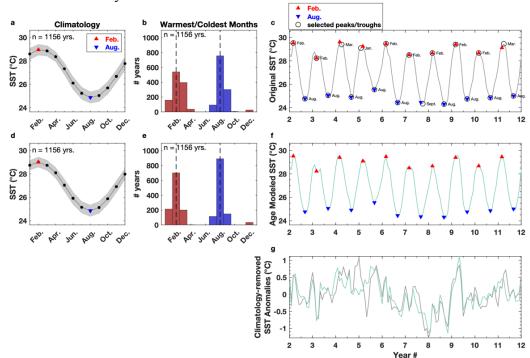

326 We apply the age model algorithm to assess the impact on interannual variance using SST from the 327 grid points nearest to Vanuatu and Christmas Island (Figures 4-5; see Supporting Figures 1-2 for  $\Delta \delta^{18}O_{\text{pseudocoral}}$ ). Simulated SST at Vanuatu shows a clear annual cycle with the climatological 328 329 warmest month occurring in February (coldest in August) (Figure 4a). The algorithm does well in identifying summer and winter in Vanuatu (Figure 4c), but at Christmas Island, where the annual 330 cycle is smaller (Figure 5a) the algorithm encounters more difficulties in identifying seasonal extrema 331 332 due to the relatively large amplitude of interannual variability (Figure 5b). Uncertainty in the age model of a coral record results when a common assumption in coral age modeling that the 333 334 climatological warmest/coldest months do not change is violated.

335

To show how this uncertainty manifests, we show the spread in the distribution of warmest/coldest months. The spread in the distribution of summer/winter months at Vanuatu (Figure 4b) is narrow, so the algorithm has more success in identifying the correct calendar month in the extrema in the timeseries. That said, there is still incorrect month assignment in the age model. For example, March is the actual warmest month in model year 4, but the age model algorithm assigns the month of 341 February to the SST peak (Figure 4c). In contrast, the distribution of warmest/coldest months at 342 Christmas Island (Figure 5b) is broad, so there is much more error in assigning the correct calendar month to extrema. In worst-case scenarios, model years with strong El Niño events have a small, 343 nearly absent annual cycle with SSTs during boreal winter surpassing the climatological summertime 344 maximum values. Without constraining the approximate number of years, it is easy to miss weak 345 troughs during boreal winters with El Niño events, and therefore years. These age model assumptions 346 can vield large differences (~10-30%) in interannual variance when the climatology of the age 347 348 modeled time series (Figure 5d, 5f) is removed to generate SST anomalies (Figure 5g).

349

Our age-model algorithm is deterministic, meaning that for a given Sr/Ca or  $\delta^{18}$ O input series the age 350 351 model will iteratively find a single solution that meets the constraints provided by the user. In the context of the full coral PSM presented here, multiple realizations of age modeled pseudocoral output 352 can be generated by first perturbing the PSM input with the variable growth rate algorithm (Section 353 354 3.1). Alternatively, the user can follow the protocol of the Comboul et al. [2014] banded age model and perturb the number of years constraint within error. 355

356 357 Figure 4. Age modeling of pseudocoral SST at Vanuatu. Climatology (black)  $\pm 1\sigma$  (shading) for the original (a) and age 358 modeled (d) SST output for the grid point nearest Vanuatu in the LME 850 control (n = 1156 years). Histogram of the warmest (red bars) and coldest (blue bars) month for each individual year in the 850 control (b) and the age modeled SST 359 360 output (e). The climatological warmest/coldest months (dashed vertical lines) do not always equal the actual 361 warmest/coldest month in each year. 10 years of the original monthly SST (c, gray line) and age modeled SST (f, teal 362 line). Triangles in (a, c, d, f) indicate the climatological warmest (Feb.) and coldest (Aug.) months. The black circles in 363 (c) indicate the peak/troughs identified by the age model algorithm, and the adjacent text labels indicate the calendar 364 month at each critical point. The critical points in (c) are assigned the climatological warmest (Feb.) and coldest (Aug.) 365 months, and the data is linearly interpolated in between the critical points to generate the age modeled time series in (f). 366 The triangle markers in (f) better line up with the actual peaks and troughs in the age modeled time series compared to 367 the original environmental input in (c). (g) Monthly SSTA for the original input (black) and age modeled pseudocoral 368 SST (teal). In this and all subsequent figures, anomalies are with respect to the climatology of the full-length control run. 369 The warmest/coldest month distributions in (b) and (e) are wider than a single month, and is directly related to the loss of

370 interannual variance in (g).

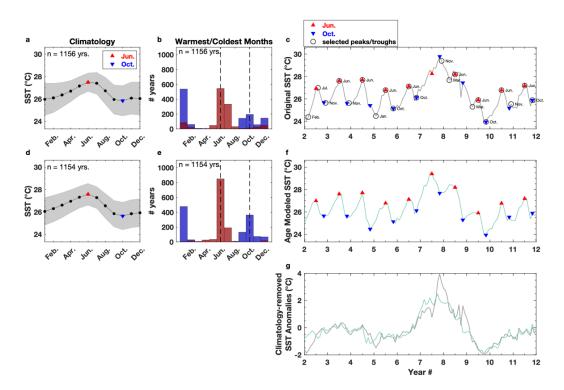

Figure 5. Age modeling of pseudocoral SST at Christmas Island. Same as Figure 4 except for the grid point nearest to
Christmas Island. Triangles in (a, c, d, f) indicate the climatological warmest (Jun.) and coldest (Oct.) months. Years with
strong El Niño events (e.g. model years 8 and 9) have a reduced annual cycle and a small and/or absent trough during
boreal winter, leading to incorrect month assignment in (f) and a reduction in interannual variance in (g).

### 377 4. Results & Discussion

378 Our coral PSM quantifies how analytical and calibration errors, variable growth rates, and age 379 modeling assumptions transduce input climate signals and impact interannual variance, and subsequently estimates of ENSO variability. Tropical reefs are point sources for paleoclimate 380 381 reconstructions; whereas, with climate model output we can advantageously run the coral PSM at 382 every grid point in the tropical Pacific to identify regional patterns. Broad regions of the tropical Pacific exhibit distinct patterns when the original environmental inputs are perturbed using the coral 383 384 PSM. We separate the identified patterns into three sections: changes in the standard deviation of 385 monthly anomalies as recorded by corals, decadal and longer changes in ENSO variability, and decadal and longer changes in ENSO variability as recorded by corals. 386

### 387

376

### 388 4.1 Quantifying Changes in Interannual Variability: Monthly Standard Deviation

389 The percent change in standard deviation between the perturbed pseudocorals and the original SST 390 or  $\Delta \delta^{18}O_{\text{pseudocoral}}$  climatology-removed anomalies is a method used to quantify changes in variance. The percent change (Figure 6) is calculated using the median standard deviation value for n391 392 realizations of the perturbed pseudocoral monthly anomaly time series, and highlights site dependencies in the results. The changes in interannual variance between the original environmental 393 inputs and the coral PSM output at a given location is linked to both the amplitude of the interannual 394 395 signal and the annual cycle. Analytical and calibrations errors (Section 3.2) cause a systematic increase in interannual variance for pseudocoral SST<sub>Sr/Ca</sub> (Figure 6b) and  $\Delta\delta^{18}O_{pseudocoral}$  (Figure 6f) 396 compared to the original environmental inputs. Regions of the Pacific with a large interannual signal 397

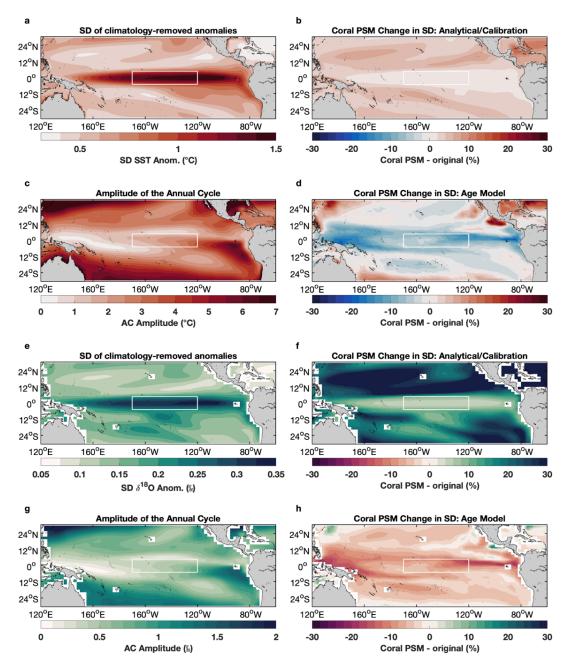

(Figure 6a, 6e) are less impacted by analytical/calibration errors compared to regions with a smallerinterannual signal.

400

401 The increase in annual cycle regularity induced by the age model (Section 3.3) broadly tends to cause a decrease in interannual variance across most of the tropical Pacific (Figure 6d, 6h). The largest 402 403 percent change in standard deviation occurs in the central Pacific and eastern Pacific cold tongue 404 regions where ENSO events can lead to climatological coldest months that are warmer than the climatological warmest months. It is thus difficult to identify a trough in the geochemical data and 405 406 accurately assign a month to the data when age modeling (Section 3.3). The age model effects are 407 particularly exacerbated in the CESM-LME due to biases in the amplitude of ENSO events [Otto-Bliesner et al., 2016]. Conversely, pseudocorals at sites with a larger annual cycle and less variable 408 409 distribution of warmest and coldest months have a smaller reduction in interannual variance compared 410 to the original environmental input (Figure 6d, 6h). Outside of the tropics, however, sites that have 411 multiple consecutive months with approximately the same average SST value experience an increase in variance (Figure 6d). For a given site, the magnitude of the percent change is typically larger for 412  $\Delta \delta^{18}O_{pseudocoral}$  compared to SST given that  $\delta^{18}O$  is multivariate and may have contributions from SSS 413 that may be a few months out of phase with SST [Gorman et al., 2012] (Figure 6d versus 6h). 414

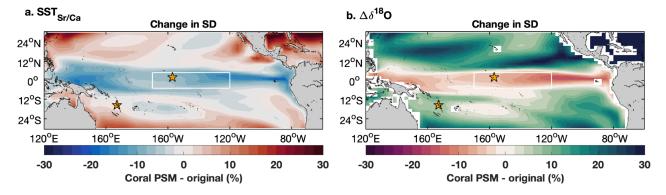

415

416 The percent change in standard deviation for the full coral PSM (Figure 7) reveals the tradeoff 417 between interannual variability and the amplitude of the annual cycle. At locations with the strongest interannual signal (equatorial sites), the loss of variance due to the age model assumptions exerts the 418 dominant influence on interannual variance for pseudocoral SST<sub>Sr/Ca</sub> (Figure 7a) and  $\delta^{18}$ O (Figure 419 420 7b). Although age model uncertainty also causes a decrease in variance in regions like the southwest Pacific, the relative magnitude of the change is compensated by the increase in variance that results 421 from analytical and calibration errors. Our results highlight that the different processes and 422 423 assumptions inherent to coral-based studies exert sizable impacts on pseudocoral interannual variance, and that the relative contributions are site dependent. While changes in the monthly standard 424 425 deviation of an individual anomaly time series can show longer term changes in ENSO [Wittenberg, 426 2009], uncertainties in coral climate reconstructions [*Emile-Geav et al.*, 2013a; 2013b] preclude such a reconstruction back in time, thus warranting an alternative metric for paleo-ENSO studies. 427

428

429 **Figure 6.** Pseudocoral SST<sub>St/Ca</sub> and  $\delta^{18}$ O changes in interannual variance. (a) Standard deviation (SD) of monthly SSTA 430 in the LME 850 control. Warm colors highlight regions with the largest interannual signal. (b) Percent change in SD 431 between pseudocoral SST<sub>st/Ca</sub> anomalies perturbed with analytical and calibration errors and the SD of the unperturbed 432 SST anomalies. (c) Amplitude of the annual SST cycle in the LME 850 control. (d) Percent change in SD between age 433 modeled pseudocoral SST<sub>Sr/Ca</sub> anomalies and the original, unperturbed SST anomalies. (e) SD of monthly forward modeled  $\Delta \delta^{18}O_{\text{pseudocoral}}$ . (f) Percent change in SD between pseudocoral  $\delta^{18}O$  anomalies perturbed with analytical errors 434 435 and the SD of the unperturbed  $\Delta \delta^{18}O_{\text{pseudocoral}}$  anomalies. (g) Amplitude of the annual  $\Delta \delta^{18}O_{\text{pseudocoral}}$  cycle in the 850 436 control. (h) Percent change in SD between age modeled pseudocoral  $\Delta \delta^{18}$ O anomalies and the original, unperturbed  $\Delta \delta^{18}$ O 437 anomalies. The percent change in SD for the full-length time series ( $\sim 1156$  years) is reported. The SD for the coral PSM 438 output is the median of 1000 realization in (**b**, **f**) and 1 realization of the deterministic age model (**d**, **h**). Colormaps in this 439 and all subsequent maps use the cmocean: colormaps for oceanography toolbox [Thyng et al., 2016]. The Niño 3.4 region 440 is outlined by a white box (**a-h**). The changes in interannual variance from analytical/calibration errors (**b**, **f**) is related to 441 the amplitude of the interannual signal  $(\mathbf{a}, \mathbf{e})$ , whereas the change in variance from age modeling  $(\mathbf{d}, \mathbf{h})$  is linked to the 442 amplitude of the annual cycle (c, g).

443 444

450

Figure 7. Changes in interannual variance for the full coral PSM. Percent change in SD between pseudocoral  $SST_{Sr/Ca}(\mathbf{a})$ 445 and  $\Delta \delta^{18}$ O (b) anomalies perturbed with variable growth rates, analytical/calibration errors, and the age modeling 446 algorithm, and the original, unperturbed environmental input (n = 100 realizations). Selected sites at Christmas Island 447 (2°N, 157°W) in the central Pacific, and Vanuatu (16°S, 167°E) in the southwest Pacific are indicated with gold stars. 448 The white box outlines the Niño 3.4 region. The percent change in SD for the full coral PSM reveals the tradeoff between 449 interannual variability and the amplitude of the annual cycle (Figure 6).

#### 451 4.2 Quantifying Changes in ENSO Variability: Decadal+

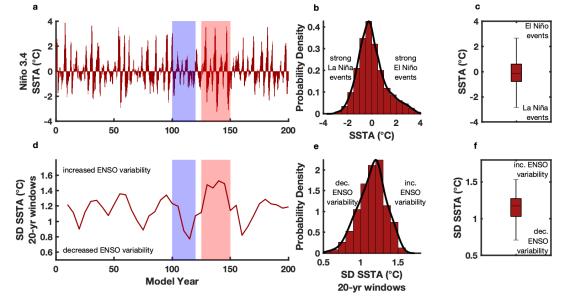

Although precise month-to-month variations of SST in the Niño 3.4 region are a sought-after target 452 453 for ENSO studies, this is difficult to reconstruct back in time using a limited number of coral proxy records with age uncertainties. Previous studies have used sophisticated statistical techniques on 454 corals from the last millennium and still had an appreciable degree of uncertainty in the reconstruction 455 [Emile-Geav et al., 2013a; 2013b]. Fossil corals with absolute age errors on the order of 1% make a 456 month-to-month reconstruction virtually impossible on  $10^3$  year and longer timescales. We address 457 this challenge by building upon the procedure suggested in *Trenberth* [1997] and use descriptive 458 459 statistics and probability theory to quantify changes in ENSO variability on the timescale of decades. Indeed, the technique of looking at changes in ENSO over windows in the past has already been 460 employed using corals from the central Pacific [Cobb et al., 2013]. In this sub-section, we formalize 461 462 the technique to quantify changes in ENSO in reconstructions and then couple it to the coral PSM in Section 4.3. 463

464

We demonstrate different methods of quantifying changes in ENSO variability using climatology-465 removed SST anomalies averaged across the Niño 3.4 region (Figure 6, box) as an illustrative 466 467 example to show how the different techniques all agree on the changes in ENSO, but have different applicability. We restrict the time series (Figure 8a) to the first 200 years purely for discussion 468 purposes in this section but use the entire control run for the remainder of the analyses. During El 469 470 Niño (La Niña) events, the Niño 3.4 region experiences positive (negative) SST anomalies that peak during boreal winter while the western Pacific experiences negative (positive) excursions [Trenberth, 471 472 1997]. Strong El Niño and La Niña events yield SST anomalies that fall into the tails of the SSTA 473 distribution (Figure 8b, 8c). An increase in the frequency and/or magnitude of strong ENSO events will increase the width of the SSTA distribution, and result in a larger standard deviation. This 474 475 technique works best on data that has small uncertainty in the time domain or in the interpretation. 476

477 Here we introduce a calculation to quantify fluctuations in SSTs from the Niño 3.4 region on decades 478 or longer timescales, as these changes are more readily captured in paleo-ENSO reconstructions using 479 archives with uncertainties. Longer-term changes in the amplitude and frequency of large SST anomalies can occur for decades or longer intervals, which we call decadal+ variability. As an 480 481 example of the types of changes that this technique captures, model years 100-120 (Figure 8a) has

smaller amplitude SSTA compared to the frequent large amplitude anomalies in model years 125-482 150. These changes occur in the absence of external forcing, as this is an unforced model simulation, 483 and they likely result from complex interactions between ENSO and other internally driven modes of 484 variability [Wittenberg, 2009; Wittenberg et al., 2014; Sun and Okumura, 2019]. We quantify 485 decadal+ changes in ENSO variability using the running standard deviation of climatology-removed 486 monthly SSTA of 20-year windows averaged across the Niño 3.4 region ( $\sigma_{Niño3.4-SSTA}$ ; Figure 8d) 487 [Okumura et al., 2017]. Here we use a 20-year running standard deviation as many fossil coral record 488 lengths are short, but our approach is applicable to investigating changes in variability over longer 489 time intervals. Larger  $\sigma_{Nino3.4-SSTA}$  values indicate increased ENSO variability, whereas smaller 490  $\sigma_{Nino3.4-SSTA}$  values indicate decreased ENSO variability during a time interval. The wide range of 491 internal ENSO variability within the CESM-LME 850 control is reflected in the width of the σ<sub>Niño3 4-</sub> 492 ssTA distribution (Figure 8e, 8f). We posit that longer term, decadal+ changes in ENSO variability, as 493 reflected by  $\sigma_{Nino3.4-SSTA}$  and the distribution of standard deviation values (Figure 8f), is a feasible 494 495 target for coral-based paleoclimate reconstructions since this metric reduces the influence of 496 uncertainties, especially temporal.

499 Figure 8. Quantifying changes in internal ENSO variability. (a) Monthly SSTA averaged across the Niño 3.4 region in 500 the 850 control (200-yr subset shown for clarity). Distribution of Niño 3.4 SSTA depicted as a histogram/PDF (b) and 501 box plot (c) for the full-length control (1156 years). (d) 20-yr running standard deviation of Niño 3.4 monthly SSTA 502  $(\sigma_{Nifio3.4-SSTA})$ . Shaded portions in (**a**, **d**) highlight two intervals with more (red) and less (blue) internal ENSO variability. 503 Distribution of  $\sigma_{Nino3.4-SSTA}$  values depicted as a histogram/PDF (e) and box plot (f). Higher SD values indicate increased 504 ENSO variability, whereas lower SD values indicate decreased variability. PDFs in (b, e) are based on a kernel density 505 estimation method [*Parzen*, 1962]. The lower and upper bounds of the boxes in (c, f) correspond to the  $25^{\text{th}}$  and  $75^{\text{th}}$ 506 percentiles and the center line indicates the median. The whiskers in (c, f) represent the 1.5 x inter-quartile range (IOR). 507 Outliers greater than 1.5xIQR are omitted for clarity. The running SD of monthly anomalies (f) is a metric for decadal+ 508 changes in interannual variability.

509

### 510 4.3 Quantifying Changes in ENSO Variability using Corals: Decadal+ with PSM

511 The coral PSM provides a tool to investigate how various uncertainties not only impact interannual

512 variability locally, but also how the uncertainties broadly impact the ability of a pseudocoral to 513 capture decadal+ changes ENSO variability. On interannual timescales, corals from circum-Pacific

514 locations are influenced by ENSO, local variability, and how corals themselves records climate

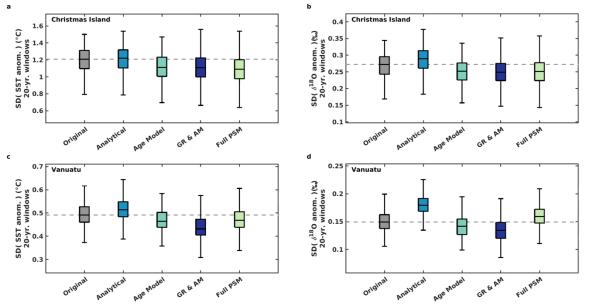

514 locations are influenced by ENSO, local variability, and now colars themselves records climate 515 (Section 1) Our aeral DSM addresses some of these confounding influences by quentifying how

515 (Section 1). Our coral PSM addresses some of these confounding influences by quantifying how

analytical and calibration errors, variable growth rates, and age modeling assumptions modify input 516 517 climate signals and impact interannual variance (Section 4.1). The running standard deviation of climatology-removed anomalies is presented as a more applicable metric in paleoclimate 518 519 reconstructions for capturing temporal changes in interannual variability as well a means to provide constraints on the range of internal variability (Section 4.2). A running or windowed standard 520 deviation is also advantageously poised to handle short (several decades or less) and/or discontinuous 521 coral records, and has previously been employed for fossil coral records spanning thousands of years 522 523 ago (the mid- to late-Holocene) [Cobb et al., 2013].

524

538

525 526 Figure 9. The impact of coral PSM uncertainties on interannual variance. Box plots showing the distribution of 20-yr 527 running standard deviation values for pseudocoral SST<sub>sr/Ca</sub> (a, b) and  $\delta^{18}$ O (c, d) anomalies across all pseudocoral 528 realizations for the Christmas Island (a, c) and Vanuatu (b, d) grid points. The growth rate and age model (GR & AM), 529 analytical/calibration, and full PSM include the results for 1000 realizations. The deterministic age modeled results are 530 shown for 1 realization. The full PSM is determined by consecutively running the growth rate algorithm, applying 531 analytical/calibration error, and then age modeling all 1000 pseudocoral  $SST_{sr/Ca}$  or  $\Delta\delta^{18}O_{pseudocoral}$  realizations. The lower 532 and upper bounds of the boxes correspond to the 25<sup>th</sup> and 75<sup>th</sup> percentiles and the center line indicates the 50<sup>th</sup> percentile. 533 The whiskers represent 1.5xIQR. Outliers greater than 1.5 x IQR are omitted for clarity. Dashed horizontal gray lines 534 indicate the median SD for the original environmental inputs. The median 20-year running standard deviation of SST<sub>Sr/Ca</sub> 535 and  $\Delta \delta^{18}O_{pseudocoral}$  anomalies illustrates how the various PSM subcomponents systematically increase or decrease 536 interannual variance. The length of the box and whiskers encapsulates information about the range of simulated internal 537 variability.

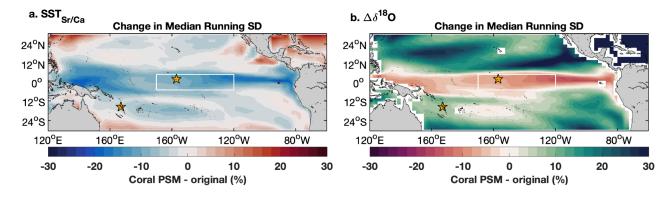

The 20-year running standard deviation of  $SST_{Sr/Ca}$  and  $\Delta \delta^{18}O_{pseudocoral}$  anomalies for Christmas Island 539 and Vanuatu (Figure 9) confirms that the various PSM subcomponents systematically impact 540 interannual variance while also encapsulating information about the range of simulated internal 541 542 variability. As with Niño 3.4 monthly SSTA (Figure 8f), the median standard deviation value of the original environmental inputs (Figure 9 gray boxes) indicates the overall amplitude of interannual 543 544 variance at a site, whereas the height of the box and whiskers indicate the degree of internal variability. Christmas Island expectedly has a higher median standard deviation value and a larger 545 spread compared to Vanuatu given that the site experiences larger interannual SST (Figure 6a) and 546  $\delta^{18}$ O (Figure 6e) signals. Perturbing the original SST and  $\Delta\delta^{18}$ O<sub>pseudocoral</sub> time series at Christmas 547 548 Island and Vanuatu with analytical and calibration errors (Section 3.2) systematically increases interannual variance (Figure 9 light blue) as quantified by the shift in the median standard deviation 549

value compared to the original environmental inputs. Incorrect assumptions about the timing of the 550 warmest and coldest month assignment in the age model (Section 3.3) decreases interannual variance 551 (Figure 9 teal). We do not isolate the impact of variable growth rates as the algorithm generates a 552 "pseudodepth" vector (Section 3.1) that is not readily subset into 20-year windows. Instead, the 553 original environmental input is perturbed with variable growth rates and then processed by the age 554 model algorithm to generate multiple realizations (Figure 9 dark blue). The combined influence of 555 variable growth rates and the age model assumptions causes a systematic decrease in interannual 556 557 variance at both sites.

558

Although each individual sub-model of the PSM causes a systematic change in interannual variance 559 560 at both Christmas Island and Vanuatu, the relative increase or decrease in the interannual signal (median standard deviation) for the full PSM, or the summation of the effects from the sub-561 components, is site dependent. These site dependencies are revealed when expanding the pseudocoral 562 network to the entire tropical Pacific (Figure 10). For similar reasons discussed in section 4.1, the 563 interannual variance change is closely related to the tradeoff between the magnitude of the interannual 564 cycle and the amplitude of the annual cycle. 565

567 568

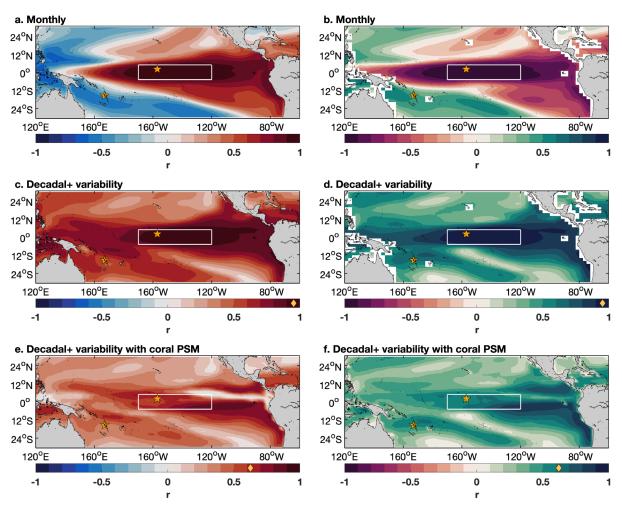

Figure 10. Changes in interannual variance for the full coral PSM. Percent difference in the median 20-year running 569 standard deviation between pseudocoral SST<sub>Sr/Ca</sub> (a) and  $\Delta\delta^{18}O$  (b) anomalies perturbed with variable growth rates, 570 analytical/calibration errors, and the age modeling algorithm, and the original, unperturbed environmental input (n = 100 571 realizations). Gold stars indicate select sites at Christmas Island and Vanuatu. The white box indicates the Niño 3.4 region. 572 The percent change in standard deviation for the full coral PSM reveals the tradeoff between interannual variability and 573 the amplitude of the annual cycle. The patterns displayed here are similar to those of Figure 6, indicating that the two 574 variability metrics yield consistent results. 575

576 We correlate Niño 3.4 SSTA with the pseudocoral realizations to demonstrate how corals from locations around the tropical Pacific record changes in ENSO, and begin with the familiar month-to-577 578 month calculation. The correlation of local SST or SSS anomalies with Niño 3.4 SSTA is canonically used to demonstrate the ENSO sensitivity at a site. A consistent pattern of response over the 1156-579 580 year-long control is an inverse temperature relationship between the central/eastern and western 581 tropical Pacific with monthly SSTA from the Niño 3.4 region (Figure 11a). Forward modeled monthly  $\Delta \delta^{18}O_{\text{pseudocoral}}$ , a function of SST and SSS, also covaries with Niño 3.4 SSTA (Figure 11b) with the 582 same pattern of response as SSTA (Figure 11a). For example, during El Niño events the central and 583 eastern Pacific experience negative  $\Delta \delta^{18}O_{pseudocoral}$  anomalies indicating the combined impact of 584 warmer and fresher conditions, while the western Pacific experiences positive  $\Delta \delta^{18}O_{pseudocoral}$ 585 excursions indicative of colder and more saline conditions [Fairbanks et al., 1997]. As previously 586 discussed, the month-to-month correlation with Niño 3.4 SSTA is more applicable for observations 587 or model output with no uncertainty in the time domain. Some of the uncertainties in coral proxy data 588

can be circumvented by instead shifting the focus to the ability of a coral to capture ENSO variabilityon decadal+ timescales (Section 4.2).

591

592 Unlike the month-to-month maps, Niño 3.4 SSTA and the running standard deviation of SST<sub>Sr/Ca</sub> and  $\Delta \delta^{18}O_{\text{pseudocoral}}$  anomalies on decadal+ timescales are positively correlated across much of the tropical 593 Pacific (Figure 11c, 11d). The boomerang-shaped monthly SSTA correlation pattern that 594 595 distinguishes the western Pacific from the central/eastern Pacific (Figure 11a) essentially disappears 596 when examining how different regions of the Pacific track decadal+ changes in ENSO variability. In 597 the decadal+ calculation of ENSO variability, a significant positive correlation coefficient between  $\sigma_{\text{Niño3.4-SSTA}}$  and the running standard deviation of monthly SST (Figure 11c) or  $\Delta\delta^{18}O_{\text{pseudocoral}}$  (Figure 598 11d) anomalies indicates that when ENSO variability increases or decreases in the Niño 3.4 region. 599 600 interannual variability at a given location tends to pace with those changes. The correlation with  $\sigma_{Nino3.4-SSTA}$  for the pseudocorals perturbed by the full coral PSM are expectedly smaller than the 601 602 original PSM inputs, but importantly, the temporal relationship with changes in SST variability in the Niño 3.4 region is broadly preserved for both pseudocoral SST<sub>Sr/Ca</sub> (Figure 11e) and  $\Delta \delta^{18}$ O<sub>pseudocoral</sub> 603 604 (Figure 11f) at many localities spanning the tropical Pacific despite all of the calculated coral 605 uncertainties. This highlights the strength of corals in their ability to capture decadal+ changes in 606 ENSO variability.

607

608 Figure 11. Correlation between Niño 3.4 SSTA and values at each grid point. Monthly Niño 3.4 correlated with monthly 609 values for SSTA (a) and monthly values of forward modeled pseudocoral  $\Delta \delta^{18}O_{pseudocoral}$  (b). The 20-yr running SD of 610 Niño 3.4 SSTA ( $\sigma_{Niño3.4-SSTA}$ ) with the 20-yr running SD of SSTA (c) and  $\Delta\delta^{18}O_{pseudocoral}$  anomalies (d). The 20-yr running 611 SD of Niño 3.4 SSTA with the 20-yr running standard deviation of SSTA (e) and  $\Delta \delta^{18}$ O<sub>pseudocoral</sub> anomalies (f) perturbed 612 by the full coral PSM. Colormap in (e, f) is the median correlation coefficient for 100 full PSM realizations. The Niño 3.4 613 region is outlined by a white box (a-f). The correlation coefficient averaged across all grid points within the Niño 3.4 614 region (white box) is indicated with a gold diamond in (c-f). Colormaps provide the Pearson correlation coefficient 615 [*Pearson*, 1920].  $\Delta \delta^{18}$ Opseudocoral is generated using the sensor model of *Thompson et al.* [2011] (Section 2.2.1). Gold stars 616 indicate select sites at Christmas Island and Vanuatu. Decadal+ changes in forward-modeled interannual SST<sub>St/Ca</sub> and 617  $\delta^{18}$ O variability are positively correlated with  $\sigma_{Nino3.4-SSTA}$  across much of the tropical Pacific (e, f) even with the added 618 uncertainties in our PSM, indicating that these processes do not obfuscate the target climate signal of decadal+ changes 619 in ENSO variability. 620

### 621 6. Conclusions

622 The coral PSM presented here fundamentally advances our knowledge of how corals modify 623 interannual climate signals and how they record changes in ENSO variability. This study builds upon previous work by adding new archive and observation sub-models to the full PSM framework in order 624 625 to quantitatively estimate the impact of various non-climatic processes on interannual variance in the final coral time series. Constraining such information is crucial given that estimation of interannual 626 variance is one of the primary applications of coral paleoclimatology. Our process-based coral PSM 627 explicitly incorporates an archive-based model (variable growth rates) as well as age modeling 628 629 assumptions that are used when generating a coral geochemical time series. This study applies the

new PSM framework to the CESM LME 850 control run, which serves as the environmental input. 630 The long control run allows us to include the impact of internal variability in our analyses, which is 631 not possible using the short instrumental record. Although we note that the PSM is equally equipped 632 633 to handle observational data or other climate model output. Our tools and algorithms are publicly available to the broader community to facilitate the comparison of coral geochemical data and 634 635 observational data or climate model output, as well as facilitate the reproducibility of our results, via

- 636 a GitHub repository (https://github.com/lawmana/coralPSM).
- 637

638 Our results characterize and document the ability of pseudocorals to capture decadal and longer, which we call decadal+, changes in ENSO variability. Coral proxy records of past ENSO variability 639 come from a suite of sites spanning the western, central, and eastern tropical Pacific, all of which 640 have varying signal to noise ratios with respect to ENSO. In some regions of the tropical Pacific, the 641 combination of different uncertainties can increase or decrease interannual SST<sub>Sr/Ca</sub> and  $\delta^{18}$ O variance 642 by 10-30% (Figures 7 and 10). Our major conclusions are: 643

- 644
  - 1. Analytical and calibration errors systematically increase interannual variance
  - 2. Seasonal chronological uncertainties associated with transforming coral geochemical data from the depth to the time domain acts to decrease interannual variability
- 3. Variable growth rates in conjunction with age modeling assumptions decreases interannual 647 variance 648
  - 4. The change in interannual variance at a given location is related to the interannual signal and the amplitude of the annual cycle
- 650 651

649

645

646

652 Given that different processes exert sizable impacts on interannual variance, it is therefore most 653 appropriate to compare coral geochemical data with instrumental observations or climate model 654 output processed through this PSM. Nevertheless, despite the three uncertainties investigated in this study, the temporal relationship with changes in SST variability in the Niño 3.4 region is preserved 655 for both pseudocoral SST<sub>Sr/Ca</sub> (Figure 11e) and  $\Delta\delta^{18}O_{pseudocoral}$  (Figure 11f). Importantly, decadal+ 656 changes in forward-modeled interannual SST<sub>Sr/Ca</sub> and  $\delta^{18}$ O variability are positively correlated with 657  $\sigma_{Niño3.4-SSTA}$  across much of the tropical Pacific. Despite all of the added uncertainties in our PSM, 658 these processes do not obfuscate the target climate signal of decadal and longer changes in ENSO 659 variability. This increases confidence that despite these major sources of uncertainties investigated 660 661 herein, coral geochemical records from across the tropical Pacific are useful tools to reconstruct changes in ENSO variability back in time. 662

663

664 Quantifying the range of ENSO variability experienced during different background climate states is critical as this can help constrain projections of how ENSO variability may change in the future with 665 anthropogenic warming. Paleoclimate reconstructions serve as important out-of-sample tests of 666 667 ENSO variability. The ability to characterize past and future changes in ENSO variability benefits from proxy system modeling studies such as this that incorporate information from both models and 668 proxy records. By putting climate model output and proxy data on a level playing field, we can 669 670 reconcile the agreement between climate models and proxy-inferred responses and take an important step toward predicting how ENSO will respond to future radiative forcing. 671

### 682 Author Contributions

A.E.L led the project and wrote the manuscript. A.E.L generated the figures and interpreted the results
with input and feedback from all authors. A.E.L and C.A.C developed the MATLAB® code for the
growth rate, analytical/calibration, and age model algorithms for the coral PSM with initial counsel
from S.G.D. T.M.Q, J.W.P., S.G.D., and P.D.N. provided regular feedback on the analysis and
writing. J.W.P, S.G.D., and P.D.N contributed to the initial inception of the research ideas. All authors
reviewed the manuscript.

- 690 Code Availability
- 691 The MATLAB® codes that have contributed to the analysis and results in this study are publicly692 available on the GitHub repository for the lead author (<u>https://github.com/lawmana/coralPSM</u>).

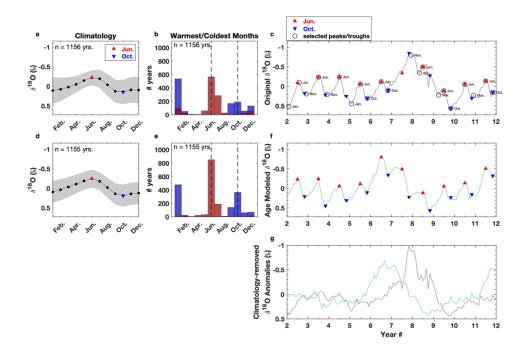

Figures S1 to S2

#### Introduction

The supporting information includes two figures that demonstrate the age model algorithm (Section 3.3) for mean-removed pseudocoral  $\delta^{18}O$  ( $\Delta\delta^{18}O_{\text{pseudocoral}}$ ). Selected sites include Christmas Island in the central equatorial Pacific (2°N, 157°W) and Vanuatu in the southwest Pacific (16°S, 167°E). Coral  $\delta^{18}O$  is forward modeled as a linear combination of sea-surface temperature and salinity using the sensor model of *Thompson et al.* [2011] (Section 2.2.1). Surface temperature and salinity data come from the CESM Last Millennium Ensemble 850 control [*Otto-Bliesner et al.*, 2016] (Section 2.1). Refer to the Section 3.3 in the main text for age modeled SST derived from coral Sr/Ca (SST<sub>Sr/Ca</sub>).

**Figure S1.** Age modeling  $\Delta \delta^{18}O_{pseudocoral}$  at Vanuatu. Same as Figure 4 in the main text except for forward modeled  $\Delta \delta^{18}O_{pseudocoral}$  at the model grid point closest to Vanuatu.

**Figure S2.** Age modeling  $\Delta \delta^{18}O_{pseudocoral}$  at Christmas Island. Same as Figure 4 in the main text except for forward modeled  $\Delta \delta^{18}O_{pseudocoral}$  at the model grid point closest to Christmas Island.
