

Stress Changes on the Garlock Fault during and after the 2019 Ridgecrest Earthquake Sequence

Marlon D. Ramos^{*1}, Jing Ci Neo¹, Prithvi Thakur¹, Yihe Huang¹, and Shengji Wei²

ABSTRACT

The recent 2019 Ridgecrest earthquake sequence in southern California jostled the seismology community by revealing a complex and cascading foreshock series that culminated in an M_w 7.1 mainshock. But the central Garlock fault, despite being located immediately south of this sequence, did not coseismically fail. Instead, the Garlock fault underwent postseismic creep and exhibited a sizeable earthquake swarm. The dynamic details of the rupture process during the mainshock are largely unknown, as is the amount of stress needed to bring the Garlock fault to failure. We present an integrated view of how stresses changed on the Garlock fault during and after the mainshock using a combination of tools including kinematic slip inversion, Coulomb stress change (ΔCFS), and dynamic rupture modeling. We show that positive ΔCFS s cannot easily explain observed aftershock patterns on the Garlock fault but are consistent with where creep was documented on the central Garlock fault section. Our dynamic model is able to reproduce the main slip asperities and kinematically estimated rupture speeds (≤ 2 km/s) during the mainshock, and suggests the temporal changes in normal and shear stress on the Garlock fault were the greatest near the end of rupture. The largest static and dynamic stress changes on the Garlock fault we observe from our models coincide with the creeping region, suggesting that positive stress perturbations could have caused this during or after the mainshock rupture. This analysis of near-field stress-change evolution gives insight into how the Ridgecrest sequence influenced the local stress field of the northernmost eastern California shear zone.

KEY POINTS

- We examine stress changes on the Garlock fault during and after the Ridgecrest sequence.
- Our models reproduce mainshock characteristics and document temporal stress change on the Garlock fault.
- Results show influence of the Ridgecrest sequence on near-field stresses in the eastern California shear zone.

INTRODUCTION

The 2019 Ridgecrest earthquake sequence involved the rupture of a left-lateral M_w 6.4 foreshock that occurred on 4 July and a right-lateral M_w 7.1 mainshock that occurred on 6 July and initiated approximately 13 km northwest of the foreshock epicenter (Fig. 1a). This sequence was characterized by the activation of multiple orthogonal fault segments that are collectively referred to as the Little Lake fault zone (LLfz). Coseismic rupture of these faults continues to produce aftershocks, but it did not influence the adjacent left-lateral Garlock fault to fail. Instead, this sequence caused as much as three

centimeters of surface creep on the Garlock fault that has been detected geodetically (Barnhart *et al.*, 2019; Ross *et al.*, 2019).

Several kinematic slip models have been developed to estimate the evolution of slip and rupture propagation during this highly complex sequence (Barnhart *et al.*, 2019; Liu *et al.*, 2019; Ross *et al.*, 2019; Chen *et al.*, 2020; Goldberg *et al.*, 2020; Zhang *et al.*, 2020). These models are consistent in the respect that a majority of foreshock and mainshock slip is limited to the upper 10 km depth. Positive stress-change amplitudes (~ 0.5 MPa) suggested from static Coulomb modeling generally coincide with the ~ 25 -kilometer-long region of creep on the central Garlock fault segment (Barnhart *et al.*, 2019). But the dynamic details of rupture and how stresses were mediated by the seismic wavefield remain hazy. The Garlock fault was apparently not near critical failure, or else we would have observed coseismic rupture there as well; this implies that the stress perturbations

were unable to bring shear stresses to overcome the static Garlock fault strength.

When the Garlock fault will slip again is a major unknown. The Garlock fault extends for ~260 km and is geometrically segmented into western, central, and eastern sections that are characterized by variations in geologic slip rate and recurrence interval (Hill and Dibblee, 1953; Davis and Burchfiel, 1973; McGill and Sieh, 1991). Astiz and Allen (1983) analyzed historical seismicity on this fault and hypothesized that a rupture on the eastern Garlock segment may be more likely given its apparent seismic gap, though both the central and western sections can independently support $M_w \sim 7$ earthquakes. Paleoseismic evidence suggests historic, nonperiodic surface rupture for the central Garlock segment (Dawson *et al.*, 2003). During the Ridgecrest sequence, different regions of the central Garlock fault segment experienced a swarm of low-magnitude earthquakes ($M_L < 3.2$; Ross *et al.*, 2019) and underwent creep. How the strain accumulation budget of the central Garlock fault was influenced by the recent Ridgecrest sequence is enigmatic and warrants further scrutiny for seismic hazard analysis. A spatial separation between the Ridgecrest mainshock and Garlock fault planes is furthermore subject to uncertainty, as is the possibility of rupture branching from a segment of the Garlock fault onto an adjacent segment or to the San Andreas fault during a future earthquake. In particular, the central and western segments have coruptured within the last 10 ka, despite a stepover structure in between them (Madugo *et al.*, 2012). Assessing the possibility of how close the Garlock fault is to failure depends on both the static and dynamic stress perturbations from the Ridgecrest sequence.

We aim to present a physically consistent picture of the stress interaction vis-à-vis the Garlock fault during and after the Ridgecrest sequence. We draw from updated kinematic inversion results that utilize geodetic, teleseismic, and near-field strong ground motion recordings to independently constrain the fault-slip amplitude, extent, and rupture initiation locations of the foreshocks and M_w 7.1 mainshock. This is then used to inform our static Coulomb stress analysis and dynamic rupture modeling efforts. Our analysis illustrates that both normal and shear stress changes were the highest on the Garlock fault at the end of mainshock rupture, and could have been responsible for the observed geodetic creep as soon as ~30 s from mainshock rupture initiation.

METHODOLOGY

Kinematic slip inversion

We use a joint slip-inversion model that is based on static Global Positioning System (GPS), teleseismic, and local strong

TABLE 1

Coulomb Stress-Change Parameters of the Mainshock and Aftershock Fault Planes

	M_w	Hypocenter	Strike	Dip	Rake	Peak Slip (m)
Mainshock	7.1	35.772° N, -117.602° E, 3 km	322	81	-170	4.7
Foreshock	6.4	35.705° N, -117.506° E, 9 km	318	88	-172	1.3
			228	81	0	0.74

Hypocenter location (latitude, longitude, and depth) and maximum slip amplitude (meters) from the kinematic inversion are also listed.

ground motion datasets (Ji *et al.*, 2002). The M_w 6.4 foreshock and the M_w 7.1 mainshock are modeled with two- and single-fault plane geometries, respectively (Fig. 1). Slip along the mainshock fault occurs along a 100-kilometer-long segment that dips at $\sim 88^\circ$ (Fig. 1b). Of the two foreshock fault planes, one is nearly parallel to the strike of the mainshock (plane 1), whereas the second is perpendicular to the mainshock (plane 2; Fig. 1c; Table 1). These fault plane geometries are consistent with those estimated by the U.S. Geological Survey and do not extend deeper than 16 km depth. Geologic mapping and Interferometric Synthetic Aperture Radar (InSAR) observations of surface-breaching rupture strands during the Ridgecrest sequence suggest that our geometries are reasonable (Xu *et al.*, 2020, and references therein). We use the slip-inversion results for the foreshock and mainshock fault planes as input into our static and dynamic stress-change modeling.

Static model: Coulomb stress change

Static stress changes are the final changes in the normal and shear stresses on the fault in response to slip after all seismic waves have propagated through. Such stress changes during the foreshock and mainshock of the Ridgecrest sequence have triggered thousands of aftershocks (Ross *et al.*, 2019). Coseismic stress changes have also been known to enhance or to reduce creep after the earthquake (e.g., Allen *et al.*, 1972; Bodin and Gombert, 1994; Lienkaemper *et al.*, 1997). Barnhart *et al.* (2019) observed that an increase in the Coulomb stress change (ΔCFS) from the Ridgecrest earthquake was correlated with the surface deformation after the earthquake. Studies have also suggested that the M_w 6.4 foreshock and other large foreshocks promoted the rupture of the mainshock (Barnhart *et al.*, 2019; Goldberg *et al.*, 2020; Lozos and Harris, 2020).

To assess static stress changes, we calculate the ΔCFS using the Coulomb 3 software (Lin and Stein, 2004; Toda *et al.*, 2005). We investigate the ΔCFS caused by the foreshock on the mainshock and separate the contribution of stress change from each of the two foreshock fault planes (Plane 1 and Plane 2; Fig. 2). We use a friction coefficient of 0.6 and a depth of 5 km for the foreshock-mainshock static stress-change calculation because a majority of slip is resolved on foreshock plane 2 (Fig. 1c), which will dominate the ΔCFS amplitude.

We also calculate the ΔCFS due to mainshock slip on the Garlock fault. We represent the Garlock fault geometry as a plane with a strike, dip, and rake of 70° , 90° , and 0° , respectively.

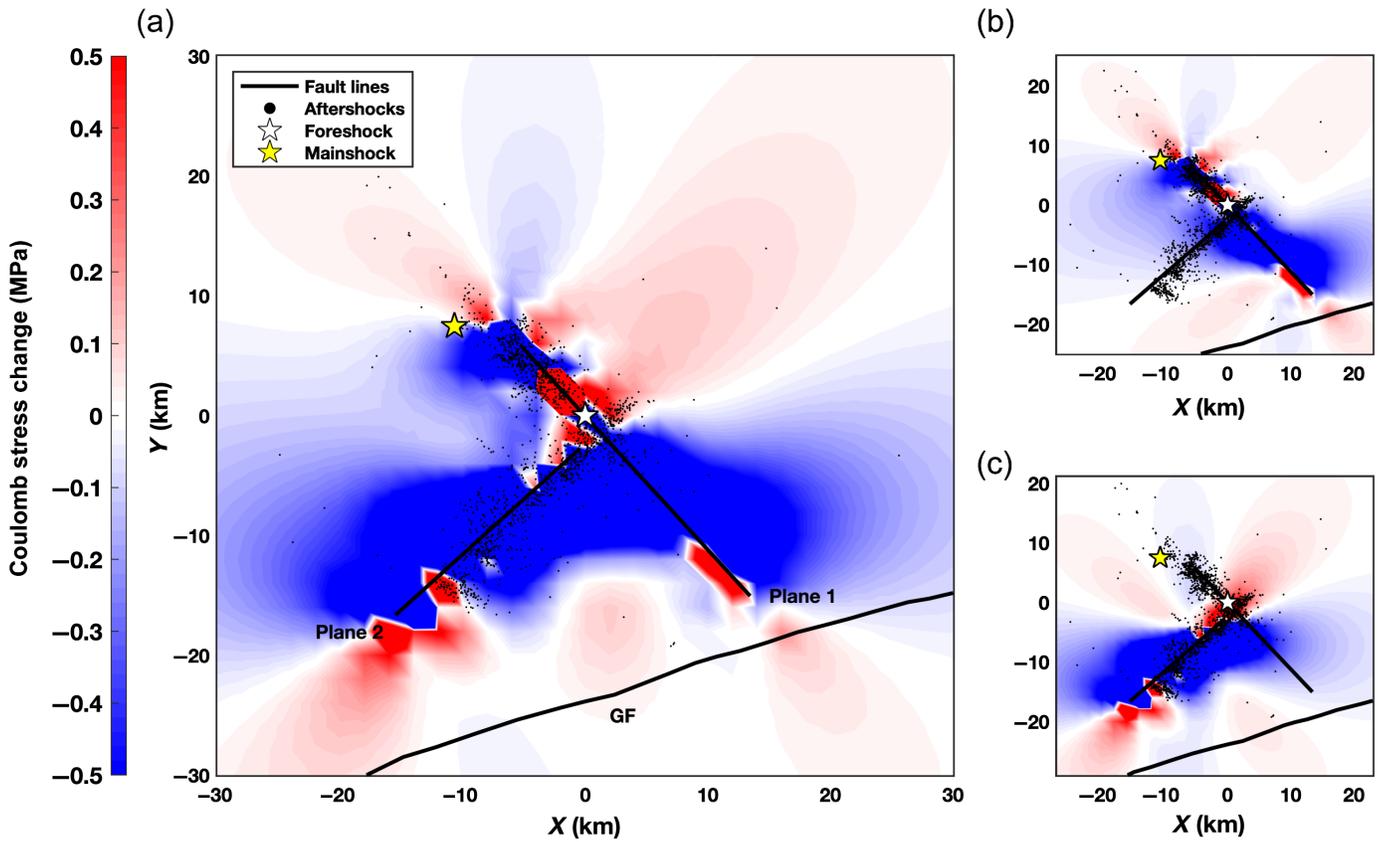

The strike of the Garlock fault varies from 68° in the east to 84° in the west (Fig. 3), but we use 70° for the receiver fault as it is the closest to the strike of the western Garlock fault segment where the cluster of aftershocks occurred. Lastly, to address uncertainty in static friction level and hypocenter depth, we also examine how varying these parameters influences our results. We compare the results from friction coefficients of 0.2, 0.4, and 0.6, and at 5 km depth, where peak slip occurred, and at 10 km depth, where the asperity with most slip extends.

Dynamic model: Initial conditions and constraints

We model the mainshock fault plane as a 100 km, planar 2D crack embedded in a homogeneous, isotropic, and linearly elastic medium with a shear wavespeed of 3.2 km/s. The model domain is composed of rectangular elements enclosed on all sides by absorbing boundaries (Fig. S1, available in the supplemental material to this article). We choose a finite-element size of 600 m with four Gauss-Lobatto-Legendre nodes to resolve dynamic rupture propagation at seismic frequencies up to 1 Hz for consistency with that resolved by the strong-motion dataset.

We select the linear slip-weakening friction law to control fault-slip evolution and utilize the 2D spectral element code SEM2DPACK to solve for dynamic rupture propagation (Ampuero, 2009). The critical-slip distance (D_c) is 0.3 m, which is constant along the fault (except for ~ 15 km around the nucleation region) and is within the plausible range of previous slip-weakening dynamic rupture simulations for other crustal earthquakes of comparable magnitude and rupture dimension (e.g., Ma and Archuleta, 2006; Tinti *et al.*, 2009; Lozos and Harris, 2020). If dynamic friction (μ_d) is below the static friction (μ_s) level, then the fault experiences a strength drop during coseismic rupture and its frictional behavior is slip weakening; conversely, if the dynamic friction is greater than static friction, there is no work available to grow the propagating shear crack and the frictional behavior is slip strengthening. The static friction coefficient is 0.5 everywhere along the fault. The fault is slip weakening ($\mu_d = 0.1$) along the central 70 km segment (35 km southeast and northwest of hypocenter) and slip strengthening ($\mu_d = 0.7$) everywhere else to prohibit rupture from breaking the entire fault.

Given that we represent a strike-slip fault as a mode II in-plane crack, our stress and friction conditions are relative to a region on the mainshock fault plane at depth. Our model aims to reproduce

the rupture propagation along the section of the fault that crosses through the main slip asperity imaged in the kinematic inversion (Fig. 4). Effective normal stress is set to a constant level of 50 MPa that is consistent with elevated pore-pressure levels in the middle of permeable fault zones (Rice, 1992).

The initial shear stress distribution is a critical ingredient for any dynamic earthquake rupture model and determines the dynamic stress drop which in turn governs slip amplitude. We first calculate the static stress drop due to fault slip given by the kinematic inversion using a computationally efficient algorithm (Fig. 4; Ripperger and Mai, 2004). Earthquakes can exhibit total or near-total stress drop due to strong dynamic weakening (e.g., Noda and Lapusta, 2013; Brodsky *et al.*, 2020), meaning that the final shear stress on the fault after an earthquake is at or very near its dynamic fault strength level (the product of effective normal stress and dynamic friction). We make this assumption to calculate our initial shear stress by adding the static stress drop to the dynamic fault strength (Fig. 4).

Rupture is artificially nucleated in the middle of the fault using the time-weakening method (Andrews, 1985). This technique requires twice the critical half-crack length ($2L_c$), an effective friction level (μ_0), and a weakening timescale (T_c) after which the prescribed nucleation is turned off and rupture spontaneously evolves according to the nonlinear interaction between fault strengths and stresses. Given the friction law parameters we assume for mode II rupture in an elastic domain, $2L_c$ is given by

Figure 2. Coulomb stress change (ΔCFS) due to foreshock planes 1 and 2 on the mainshock fault plane calculated at a depth of 5 km and with a friction coefficient of 0.6. (a) The combined effect of both aftershock fault plane slip on the mainshock. (b) The ΔCFS from plane 1, which is parallel to the main fault plane. (c) ΔCFS from plane 2, which is the northeast–southwest-striking cross fault. The aftershocks depicted are the earthquakes that occurred after the foreshock and do not include those induced from mainshock stress changes. GF, Garlock fault. The color version of this figure is available only in the electronic edition.

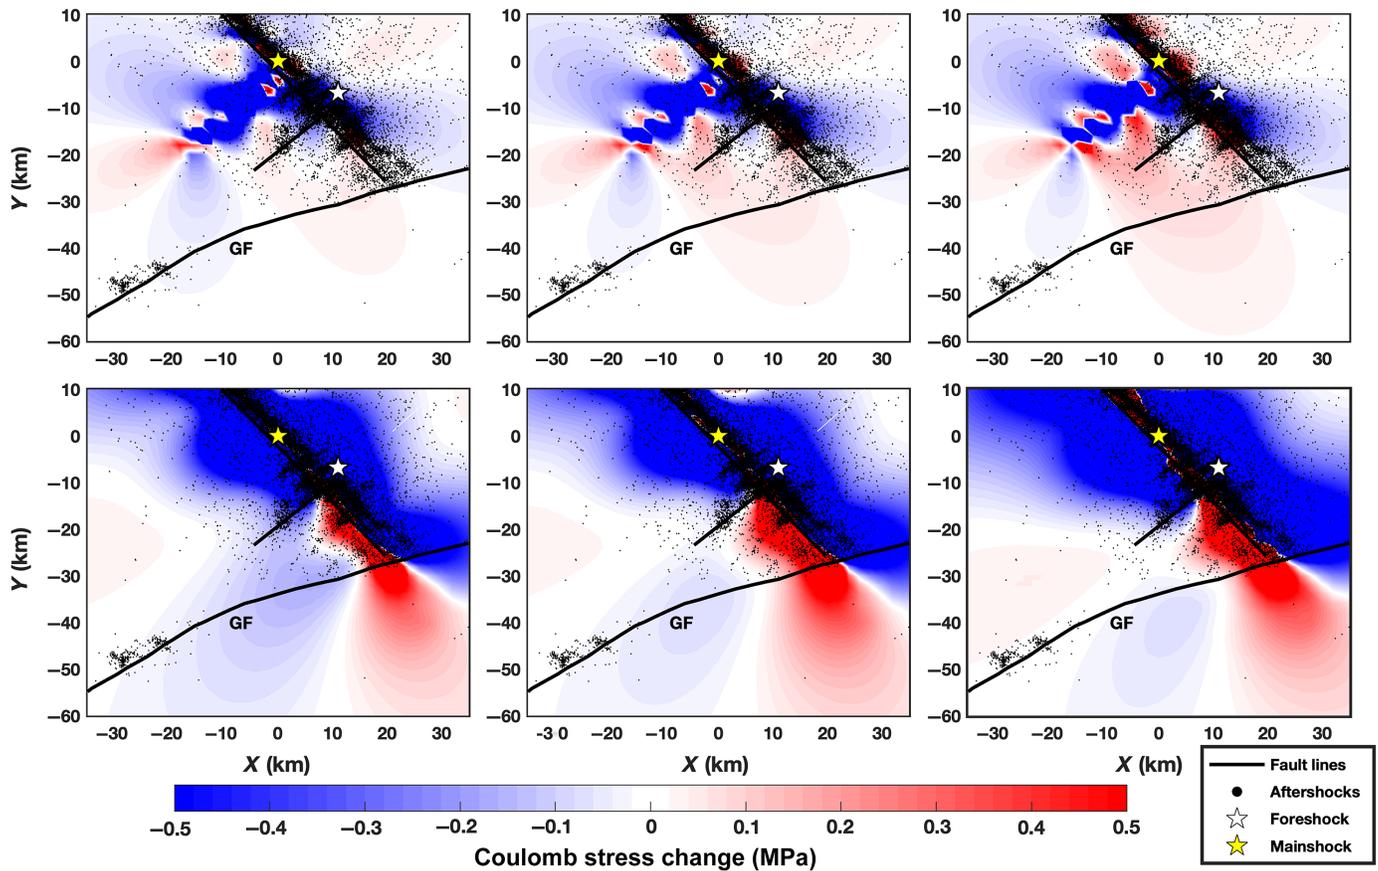

$$2L_c = \frac{2}{1 - \nu} \frac{G}{\pi} \frac{\tau_s - \tau_d}{(\tau_0 - \tau_d)^2} D_c \quad (1)$$

in which G is the shear modulus (30 GPa), ν is the Poisson's ratio, τ_s is the static fault strength, τ_d is the dynamic fault strength, τ_0 is the initial shear stress, and μ_0 is the effective friction coefficient calculated as the ratio between initial shear and effective normal stress amplitudes at the hypocenter. We determined that a $2L_c$ of 2 km (μ_0 of ~ 0.1) and T_c of 10 s are necessary to nucleate and sustain spontaneous rupture.

RESULTS

Kinematic slip inversion

Using our kinematic inversion methodology, the mainshock hypocenter has been relocated to a depth of 3 km by the arrival times of nearby strong-motion and broadband seismic stations (Fig. 1b). The aftershock hypocenter is deeper (9 km) and slip

is distributed across two fault segments (Fig. 1c). The fault parameters and hypocenters of both earthquakes are summarized in Table 1. We note that the M_w 7.1 mainshock ruptured bilaterally with a majority of slip concentrated within the upper 10 km and a peak slip amplitude of 4.7 m located ~10 km northwest of the hypocenter (Fig. 1b). There is a smaller asperity that underwent ~2.5 m of slip southeast of the mainshock hypocenter, as well. On the other hand, peak slip resolved for the foreshock is lower (1.3 m) and occurred mostly on plane 2, which is perpendicular to the mainshock fault plane (Fig. 1c).

We also compare our mainshock slip-inversion results with those from other studies of the Ridgecrest mainshock. We utilize seismic and GPS datasets to constrain the slip, which is similar to the approach by Liu *et al.* (2019). In contrast, other studies make use of a combination of seismic, high-rate GPS and InSAR (Ross *et al.*, 2019; Chen *et al.*, 2020; Goldberg *et al.*, 2020), InSAR and optimal image tracking (Barnhart *et al.*, 2019), or only seismic datasets (Zhang *et al.*, 2020). The details of slip distribution, and in particular the relative location and amplitude of maximum slip, varies between studies. The maximum slip is mostly shallower (~4 km, Barnhart *et al.*, 2019), to the northwest of (~10 km, Liu *et al.*, 2019), or slightly deeper (~5 km, Ross *et al.*, 2019) than the hypocenter location used in their inversion. The kinematic slip inversion we present resolves two primary slip patches (i.e., Fig. 1), which have similar amplitudes (4.7 and 2.5 m) and locations (northwest and southeast of hypocenter)

Figure 3. Δ CFS of the mainshock on a receiver fault of 70° strike and 90° dip, approximating the leftmost part of the Garlock fault in this figure. (Top) Δ CFS results for a 5 km depth source at friction coefficients of (left to right) 0.2, 0.4, and 0.6. (Bottom) Δ CFS results for a 10 km depth source with the same friction coefficients. to the Barnhart *et al.* (2019), Liu *et al.* (2019), and Zhang *et al.* (2020) inversion results. A major difference in maximum slip amplitude occurs between our model and the Ross *et al.* (2019) study, which estimates as much as 9 m of slip between 5 and 10 km depth. Other notable changes between our study and other's include a more widely distributed higher (>4 m) slip distribution (Chen *et al.*, 2020), or a maximum slip amplitude difference on the order of 1.5 m between what is resolved from our inversion (4.7 m) and the Goldberg *et al.* (2020) (~3.5 m) study. Such differences are most likely due to the datasets used to constrain the inversions as well as the particular inversion parameterization. Overall, our mainshock slip distribution is consistent with other published models, characterized by bilateral rupture propagation and a shallow (<10 km) slip distribution.

Static stress change

We find the foreshock increased the Δ CFS near the edges of the foreshock faults, especially at the intersection of plane 2 and mainshock fault, but our relocated mainshock hypocenter

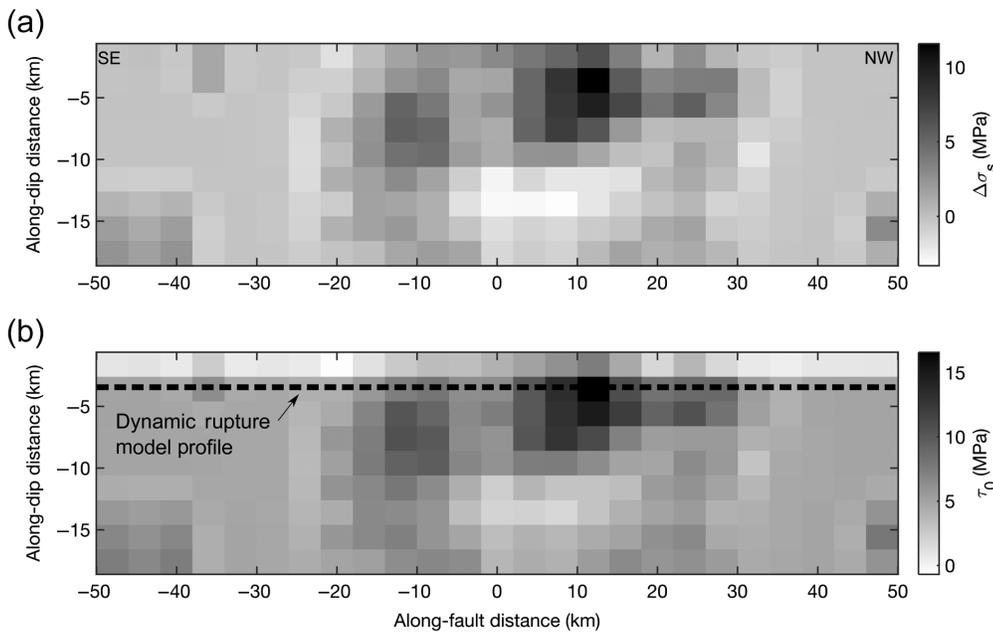

Figure 4. (a) Static stress drop and (b) initial shear stress along the mainshock fault plane. Static stress drop is calculated assuming a homogeneous Poisson medium and initial shear stress is computed using the complete stress-drop assumption. We select an initial shear stress profile through the main asperity at 3 km depth (dashed line) for our 2D dynamic rupture models.

is located in a region of slightly decreased ΔCFS (Fig. 2a and Fig. S2). However, this result depends on the method used to locate the mainshock hypocenter and its uncertainty. For instance, the Advanced National Seismic System (ANSS) comprehensive catalog epicentral coordinates agree with ours to within a kilometer but its depth is 5 km deeper than our preferred depth of 3 km, whereas the hypocenter resolved by Ross *et al.* (2019) is ~ 12 km away from the foreshock hypocenter but at a similar shallow depth (< 4 km). The hypocenters estimated by the ANSS catalog and by Ross *et al.* (2019) are located near the edges of different regions of positive ΔCFS . We also calculated the ΔCFS from both foreshock planes separately (Fig. 2b, c). Plane 2 has a much larger slip compared with plane 1, with almost twice the peak slip (i.e., 1.3 vs. 0.74 m; Table 1). However, plane 1 causes an ~ 0.5 MPa greater ΔCFS on the southeast region of the mainshock fault compared with plane 2, as plane 1 is closer (Fig. 2b). This underscores the sensitivities of the ΔCFS to input fault-slip amplitude and extent.

We further calculate the ΔCFS on the Garlock fault due to mainshock slip and assess the effect of various friction coefficients and depths on our results. Overall, we find that the friction coefficient has a relatively small (i.e., a difference within ~ 0.1 MPa) impact on our ΔCFS results for a given depth (Fig. 3). Larger friction coefficients tend to increase the ΔCFS amplitude and changes the spatial distribution of positive and negative stress changes (Fig. 3). This is similar to Barnhart *et al.* (2019), in which they found that their results are consistent for

all friction coefficients that they tested. For a given friction coefficient, changing the depth of the ΔCFS calculation from 5 to 10 km increases the ΔCFS amplitude by ~ 0.3 MPa and decreases the extent of the region of positive ΔCFS on the Garlock fault by approximately 20 km (Fig. 3). The amplitude difference is because the largest portion of mainshock slip extends to about 10 km depth, and the change in slip at this depth produces a larger ΔCFS than at 5 km depth. The region of positive ΔCFS in proximity to the creeping section of the Garlock fault is most consistent in spatial extent with that of Barnhart *et al.* (2019) when we use a friction coefficient of 0.2 and a depth of 5 km. Lastly, we find that the cluster of aftershocks on the Garlock fault are unlikely to be simply

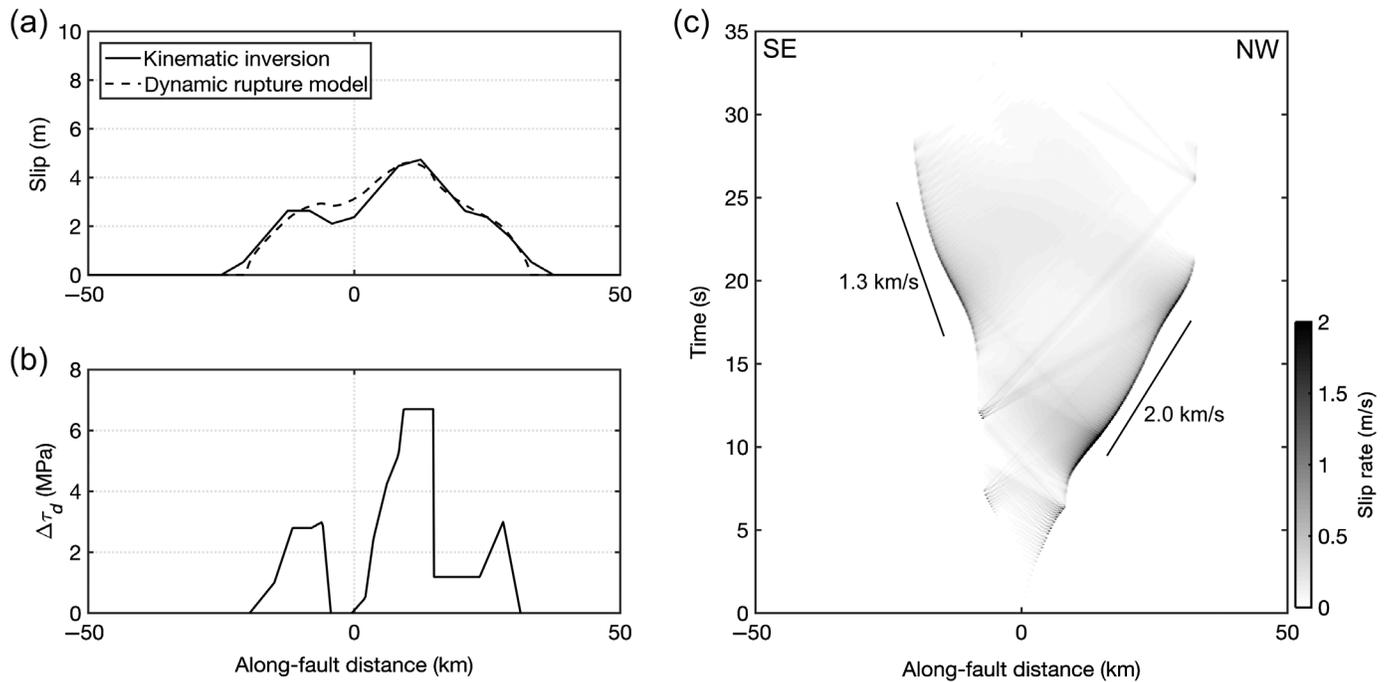

explained by ΔCFS from the mainshock as the value of the stress change can be small (< 0.01 MPa) or even negative (~ -0.1 MPa) (Fig. 3).

Dynamic earthquake rupture model

Our first goal is to explain the kinematic fault-slip distribution using rupture dynamics. We seek to reproduce the two primary patches of 2.5 and 4.7 m slip southeast and northwest of the hypocenter, respectively, (Figs. 1b and 5a). We show the rupture history until 35 s to highlight the arrest of both the northwest and southeast rupture fronts (Fig. 5).

The initial conditions and friction parameters outlined in the Methodology section gives a good agreement between the kinematically imaged and dynamically modeled slip distributions. The exception is the region near the hypocenter, where the dynamic rupture model overpredicts the kinematic slip amplitude by ~ 0.8 m (Fig. 5a). This is most likely due to our time-weakening nucleation procedure but is probably within the uncertainty of the true fault slip resolved by the kinematic inversion. The distribution in dynamic stress drop is positive for which higher slip is concentrated, and negative in a small region southeast of the hypocenter and where we impose slip-strengthening frictional behavior at the ends of the fault (Fig. 5b).

The bilateral mainshock dynamic rupture is overall heterogeneous and spatiotemporally complex (Fig. 5c). There are three major asperities (i.e., relatively high dynamic stress-drop regions) that contribute to several rupture-front accelerations (Fig. 5b,c).

The model shows a slow (<1 km/s) rupture front propagating to the southeast for the first 5 s after nucleation ceases; this southeast rupture front then accelerates to ~ 1.3 km/s before decelerating and arresting at 28 s (Fig. 5c). In contrast, the northwest rupture front propagates at a more uniform speed (~ 2.1 km/s) before decelerating and stopping at ~ 25 s. These rupture speeds are consistent with recent kinematic models that prescribe a constant sub-Rayleigh mainshock rupture speed (Liu *et al.*, 2019; Ross *et al.*, 2019; Goldberg *et al.*, 2020; Zhang *et al.*, 2020). Rupture speed depends on how much total available energy is partitioned into radiated or fracture energy during the faulting process. Slower ruptures (as observed during the Ridgecrest sequence) may be due to a relatively high fracture energy consumed on the fault, consistent with the hypothesis that the Llfz is less compliant and more energy was needed to break multiple fault segments (Perrin *et al.*, 2016; Liu *et al.*, 2019; Goldberg *et al.*, 2020). Our dynamic model shows that the mainshock rupture fronts do not exhibit slip-rate amplitudes above 4 m/s and propagate at well below the Rayleigh wavespeed.

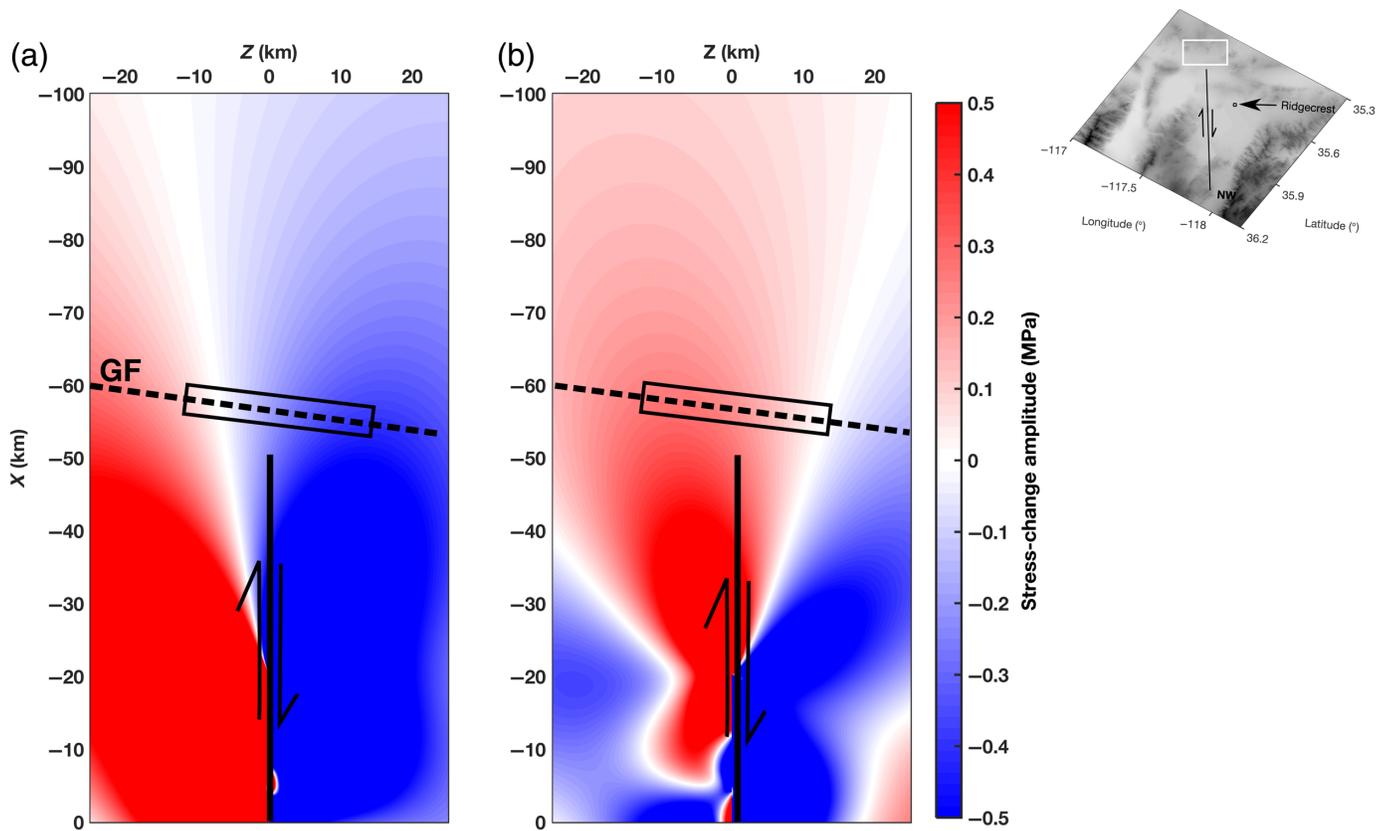

Temporal stress changes on the Garlock fault

Using our dynamic rupture model, we investigate the stress contributions to a section of the central Garlock fault during and after the Ridgecrest mainshock. Given the limitation of our modeling domain, we cannot assess far-field dynamic stress contributions from surface-wave amplitude changes. We instead focus on how the initial peak stresses carried by near-field seismic waves impacted the Garlock fault during coseismic rupture.

The 2D stress tensor in our model is for an isotropic body and yields three unique components: σ_{xx} , σ_{yy} , and σ_{xy} . Only

Figure 5. (a) Along-fault slip distribution resolved by the kinematic slip inversion (solid line) and that calculated from the dynamic rupture model (dashed line). The x-axis measures distance from where the earthquake is nucleated in our model. (b) Dynamic stress drop along the fault. Location shown in Figure 4. (c) Spatiotemporal and bilateral rupture history predicted by the dynamic rupture model. Solid lines signify average rupture-front speed. Both rupture fronts propagate at sub-Rayleigh wavespeed.

one component of the normal stress (σ_{yy}) and the shear stress (σ_{xy}) are important to be considered further in our analysis. If we place the strike of the mainshock fault plane on an east–west coordinate system, the angle between the mainshock and Garlock fault planes (measured clockwise) is approximately 110° . We therefore applied a rotation of the stress field at a particular instant in time to represent the stress perturbation the mainshock imparts to the Garlock fault (Fig. 6; see the supplemental material). When this rotation is performed at the final timestep, the rotated stress field is equivalent to the static stress change on the Garlock fault. We observe an abrupt transition from negative to positive normal static stress change as one crosses the intersection of the strike of the mainshock fault plane (Fig. 7a). The shear stress change is slightly more complex with an asymmetric stress amplitude distribution across the fault, but shows a very pronounced region of positive stress change that generally coincides with the ~ 25 -kilometer-long section of the central Garlock fault that underwent creep (Fig. 7b; Barnhart *et al.*, 2019; Xu *et al.*, 2020). To confirm our static stress-change analysis from the dynamic model, we compare it with our Δ CFS calculation and find that its orientation and amplitude are consistent (Fig. S4).

We also calculate the temporal stress change on the central Garlock fault segment during the Ridgecrest mainshock. We select one point near the creeping region on the Garlock fault (-60 km, -10 km; Figs. 7 and 8) to show how normal and shear stresses change during mainshock rupture. Although propagation spontaneously arrests at near ~ 28 s toward the southeast, we simulate rupture until 100 s to make sure stress changes relax to constant levels, which are attained at 60 s (Fig. 9). This section of the central Garlock fault begins to experience a positive normal stress change near 17.5 s (Fig. 7). During the main portion of coseismic rupture, normal stress changes reach their maximum of ~ 0.3 MPa at 32 s (Figs. 7f and 9a). In contrast, positive shear stress changes arrive at the Garlock fault in three distinct pulses (e.g., Figs. 8f and 9a). Two of these positive shear stress-change pulses arrive after the largest change in normal stress change and continue to be above the normal stress-change amplitude for the remainder of our simulation (Figs. 8 and 9a). The extrema of the normal and shear stress-change amplitudes are symmetric through time due to the alternating arrivals of compressional-wave (P) and shear-wave (SV) motions.

DISCUSSION AND CONCLUSION

We show that stress changes during and after the Ridgecrest foreshocks and mainshock may have influenced postseismic creep on the central Garlock fault segment and brought certain

Figure 6. Static stress-change field in the modeling domain rotated to the strike of the Garlock fault. (a) Normal stress and (b) shear stress. Garlock fault trace (dashed line) and Ridgecrest mainshock fault (solid line) are superimposed onto the figure. Box denotes approximate location of the creeping region (Barnhart *et al.*, 2019). regions potentially closer to coseismic failure. Our results also shed light on the temporal stress evolution on the Garlock fault due to source dynamics. Because both normal and shear stresses vary during coseismic rupture, evaluating their respective contribution is of critical importance to identifying periods when stress changes may have been favorable to engender the observed postseismic creep.

The ΔCFS results show that positive static stress changes were experienced on the central Garlock fault due to mainshock slip (Fig. 3) and are coincident with previously documented fault creep (Barnhart *et al.*, 2019; Ross *et al.*, 2019; Xu *et al.*, 2020). Among ΔCFS s calculated for different friction levels and depths, in only one case (i.e., friction level of 0.6) is a positive static stress change on the order of ~ 0.1 MPa observed adjacent to the region of the Garlock fault that experienced a sizeable aftershock swarm (Fig. 3). This may indicate that other postseismic relaxation processes or dynamic stress changes

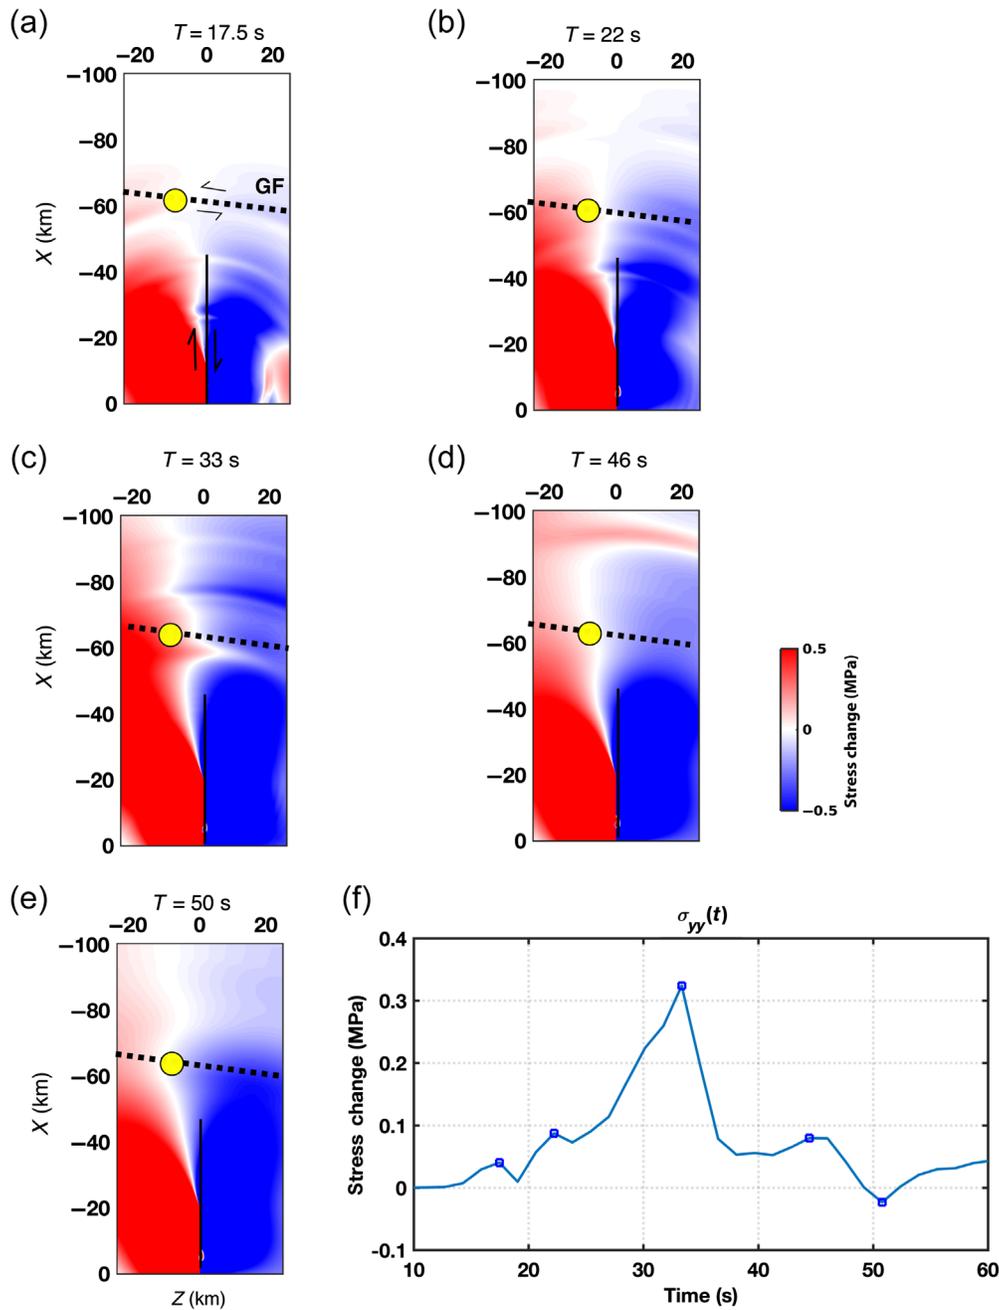

Figure 7. Normal stress changes (σ_{yy}) at various moments in time on the central Garlock fault during coseismic rupture of the mainshock. were at play to produce this aftershock pattern. Various studies have also calculated the Δ CFS of the foreshock at the mainshock hypocenter with their slip-inversion results. While Barnhart *et al.* (2019) found an increase in Δ CFS of 0.6 MPa due to the foreshock at their hypocenter, Zhang *et al.* (2020) found an increase of 0.04 MPa and Goldberg *et al.* (2020) found a <0.1 MPa increase. We find a 0.1 MPa decrease in

Δ CFS at the location of our hypocenter. The disparity in magnitude and sign of the results may be due to the fact that Coulomb stress calculations are very sensitive to the slip-inversion model used and the inferences may change depending on the location of the hypocenter, as well.

When we assess the Δ CFS through time we find that Δ CFS predominantly increases during mainshock rupture and remains at a high level afterward; this is evident from our dynamic model as the normal stress-change amplitude is mostly below the shear stress amplitude (Fig. 9b). Temporal stress changes during the mainshock rupture also support predominantly positive shear stress changes near this creeping Garlock region (Fig. 8), whereas positive and negative normal stress distributions are observed on both sides of the projected intersection of the mainshock and Garlock fault planes (Fig. 7). Our results for temporal normal and shear stress changes near the Garlock fault agree with other dynamic rupture simulations that prescribe a complex 3D fault geometry but similar constitutive friction law parameters (Lozos and Harris, 2020). Moreover, this study also documents a detailed temporal evolution of normal, shear, and Coulomb stresses impacting the central Garlock fault (i.e., Fig. 9), and not just the final stress changes after all seismic waves have been

radiated away. Because positive normal stress changes serve to strengthen the fault whereas positive shear stresses should bring the fault closer to failure, our dynamic model offers one possible scenario that creep could have occurred as soon as ~ 15 s after nucleation of the Ridgecrest mainshock when positive shear stresses began to arrive at the Garlock fault. However, this is speculative given that we do not have information on the

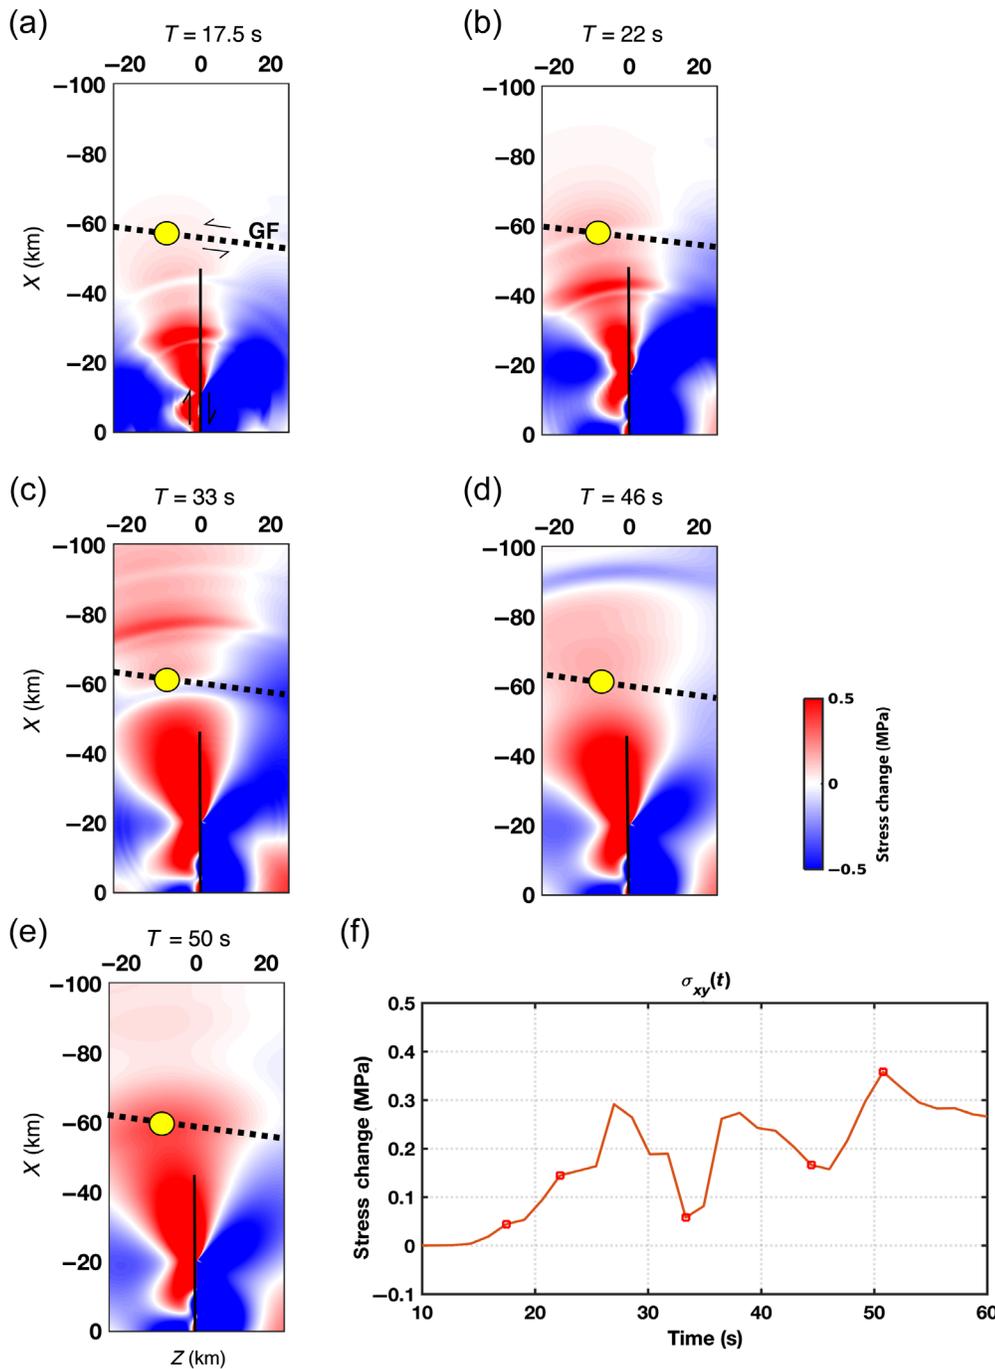

Figure 8. Similar to Figure 9, but shear stress changes (σ_{xy}) during coseismic rupture. σ_{xy} exhibits three distinct peaks in its temporal stress change on the Garlock fault at ~ 28 , 38, and 50 s. The color version of this figure is available only in the electronic edition.

absolute stress state of the Garlock fault prior to the aftershock and mainshock sequence.

Our dynamic model also suggests that the largest shear stress changes (0.3–0.4 MPa) arrived before and after the largest normal stress changes, but they are comparable in amplitude (Figs. 7–9a). Given this maximum shear stress-change amplitude at a given time, we estimate approximately

0.1 cm of slip may have been triggered near the creeping section of the Garlock fault at a depth less than 1 km (Fig. S5a). We also test a model for which creep on the Garlock fault was exceptionally shallow (<300 m depth; Schleicher *et al.*, 2019), but the distribution of creep is more heterogeneous. We still obtain a similar amount of creep that is consistent with the shear stress-change amplitude (Fig. S5b). These estimates are lower than the maximum magnitude of resolved surface creep (i.e., ~ 3 cm) documented earlier by Barnhart *et al.* (2019) and Ross *et al.* (2019), however. The creep magnitudes we estimate are furthermore only valid for a homogenous, Poisson solid and should be considered an upper bound for any given shear stress-change perturbation because our dynamic rupture model captures the region on the mainshock fault plane that experiences the greatest dynamic stress drop (~ 7 MPa; Fig. 5b). There is potential for more creep to be accommodated by successive near-field stress changes arriving at the Garlock fault during mainshock rupture, but this depends on the near-surface rheology and earthquake history of the central Garlock fault. In addition, we cannot rule out the possibility that the maximum resolvable creep was driven by cumulative or postseismic strain-rate changes not seen

by satellite observations because the smallest observation window is at least five to six days after the mainshock (Barnhart *et al.*, 2019). But extensometer data imply that it did not extend very deep into the crust, regardless of how much triggered creep was (Bilham and Castillo, 2020).

The fact that the Garlock fault did not coseismically fail could be supported by theoretical considerations to the

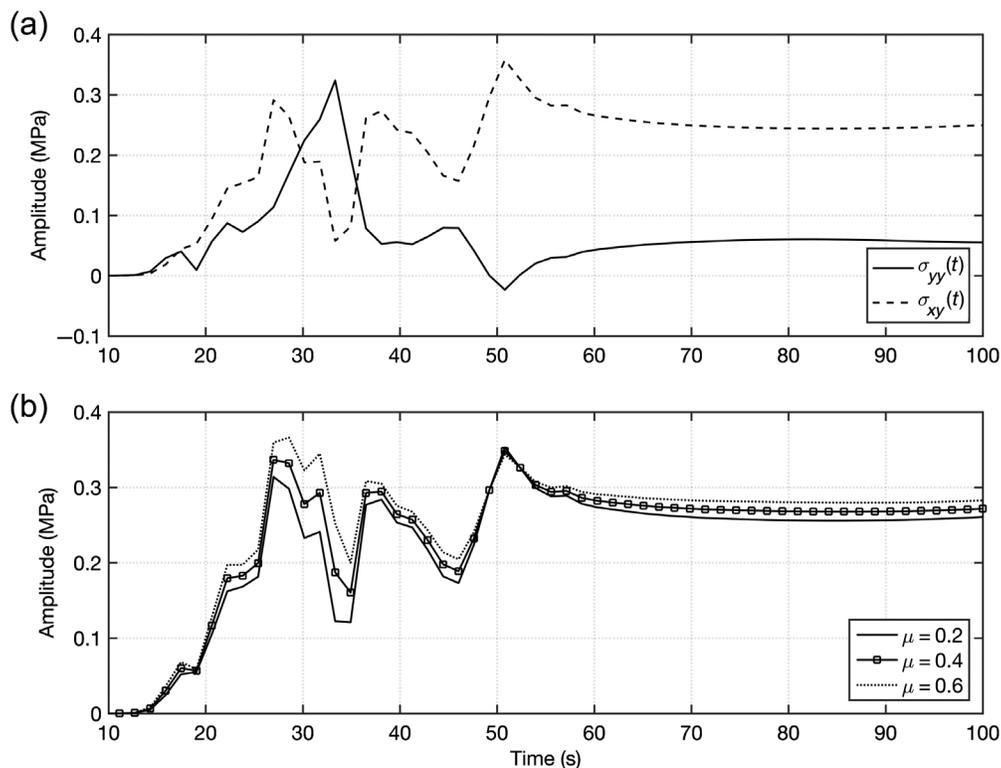

Figure 9. Stress-change evolution on a section of the Garlock fault during the entire Ridgecrest earthquake simulation. (a) Normal (σ_{yy}) and shear (σ_{xy}) stress change. (b) Temporal Δ CFS for friction coefficient levels assessed in the static stress-change analysis. Note that we plot the temporal stress change starting at 10 s because this is when the nucleation procedure ceases.

prestress state, rupture speed and fault orientation between the mainshock and Garlock fault planes, if they are connected (Poliakov *et al.*, 2002; Kame *et al.*, 2003). For a low angle of maximum horizontal shear stress (SH_max) with respect to the fault ($<45^\circ$), this prestress state encourages rupture to bifurcate toward the compressional side, whereas a higher angle ($>45^\circ$) predicts that the rupture along the extensional side is more favorable (Poliakov *et al.*, 2002). Yang and Hauksson (2013) inverted earthquake focal mechanisms in central and southern California, estimating the regional SH_max orientation lies between 0° and 5° east of north. Our dynamic rupture model predicts an average mainshock rupture-front speed to shear-wavespeed ratio of 0.4. Given that the mainshock fault plane is approximately oriented 45° west of north, such a low prestress orientation together with low rupture speed levels are not likely to encourage rupture propagation to the Garlock fault, if connected (Kame *et al.*, 2003). This mechanical argument, however, must be taken with a grain of salt considering changes in the local stress field orientation surrounding the M_w 7.1 mainshock due to the M_w 6.4, smaller foreshocks, and other seismicity. A detailed seismological analysis of foreshock and aftershock stress-tensor inversions will undoubtedly place stronger constraints on the

SH_max orientation to the mainshock fault plane, and perhaps lend credence to theoretical expectations we have briefly discussed here.

One aspect we could continue to explore in greater detail is how a fully dynamic model incorporating segmented foreshock and mainshock fault planes changes the details of the temporal stress changes on the Garlock fault. Several kinematic studies are able to fit seismogeodetic data using a segmented fault model (e.g., Liu *et al.*, 2019; Ross *et al.*, 2019; Goldberg *et al.*, 2020). Given that the Ridgecrest sequence produced multiple orthogonal faulting with some ruptures breaking the surface while others did not (Ross *et al.*, 2019), we would expect the temporal stress change to accordingly reflect this complexity. We note that the geometrically segmented 3D dynamic fault model by Lozos and Harris (2020) yields static

normal and shear stress changes on the Garlock fault that are consistent to the first order in sign and amplitude with our modeling efforts. There are small differences, but this is expected due to different initial stress parameterizations, velocity structure, and fault geometry for the mainshock and foreshock fault planes.

How the M_w 6.4 foreshock and M_w 7.1 mainshock Ridgecrest sequences changed the local stress field in southern California is a crucial question to consider given the proximity of these events to other active faults (e.g., Garlock and San Andreas). Through a unique combination of kinematic, static, and dynamic modeling, we present a physically coherent picture of the stress changes on the central Garlock fault during and after the coseismic rupture of the M_w 7.1 event. We find that positive stress changes near the creeping section of the Garlock fault are observed during and after coseismic rupture. We also show that the greatest shear stress change was comparable to the greatest normal stress change but arrived earlier during dynamic rupture; this may have promoted a section of the Garlock fault to creep even before the Ridgecrest mainshock finished slipping. Our dynamic models physically explain the resolved slip amplitude through the mainshock hypocenter and reproduce the low sub-Rayleigh rupture speeds previously suggested by kinematic rupture models.

DATA AND RESOURCES

Static stress calculations are conducted using the Coulomb 3 software available from the U.S. Geological Survey (USGS) website (<https://earthquake.usgs.gov/research/software/coulomb/>). All codes used in dynamic model postprocessing and figure creation as well as model input and output files are archived and freely accessible on University of Michigan (UM) Deep Blue (<https://deepblue.lib.umich.edu/>). All websites were last accessed in November 2019. Data used in the kinematic inversion are available upon request to Shengji Wei (shjwei@ntu.edu.sg). Some figures in this article were generated with MATLAB software or used colormap schemes from Cramer (2018, doi: [10.5281/zenodo.1243862](https://doi.org/10.5281/zenodo.1243862)). Supplemental material provides information on how we rotate stresses to the Garlock fault and show additional stress-change calculations.

ACKNOWLEDGMENTS

The authors thank Guest Editor Zachary Ross and two anonymous reviewers for their constructive comments that improved this article. This study was supported by the University of Michigan. M. D. Ramos, J. C. Neo, P. Thakur, and Y. Huang acknowledge the funding support from the National Science Foundation through Grant Awards 1663769 and 1943742. M. D. Ramos thanks P. M. Mai for providing a computationally efficient algorithm for static stress change on faults due to kinematic slip.
