## ABSTRACT

11 The emerging view of the abyssal circulation is that it associated with  
12 bottom-enhanced mixing, which results in downwelling in the stratified ocean  
13 interior and upwelling in a bottom boundary layer along the insulating and  
14 sloping seafloor. In the limit of slowly-varying vertical stratification and to-  
15 pography, however, boundary layer theory predicts that these up- and down-  
16 slope flows largely compensate, such that net watermass transformations  
17 along the slope are vanishingly small. Using a Planetary-Geostrophic Cir-  
18 culation Model that resolves both the boundary-layer dynamics and the large-  
19 scale overturning in an idealized basin with bottom-enhanced mixing along a  
20 mid-ocean ridge, we show that vertical variations in stratification become suf-  
21 ficiently large at equilibrium to reduce the degree of compensation along the  
22 mid-ocean ridge flanks. The resulting large net transformations are similar to  
23 estimates for the abyssal ocean and span the vertical extent of the ridge. These  
24 results suggest that boundary flows generated by mixing play a crucial role in  
25 setting the global ocean stratification and overturning circulation, requiring a  
26 revision of abyssal ocean theories.

## 27 1. Motivation

28 The abyssal ocean, below 2500 m, is a massive reservoir for climatically active tracers such  
29 as carbon and heat. The rates at which heat is mixed and advected into the high capacity abyssal  
30 ocean are key parameters in understanding both past climate reconstructions (e.g. Toggweiler et al.  
31 1989) and future projections of climate change (e.g. Hansen et al. 1985). Similarly, the partitioning  
32 of carbon between the deep ocean and the atmosphere is a major factor on millennial-scale climate  
33 change, whether natural (e.g. Sarmiento and Toggweiler 1984) or anthropogenic in origin (Archer  
34 et al. 1998). It is thus vital to have a firm phenomenological and dynamical understanding of the  
35 abyssal ocean's mean state.

36 The general structure of the abyssal ocean circulation is easily inferred from surface buoyancy  
37 fluxes and large-scale tracer properties (Sverdrup et al. 1942). Antarctic Bottom Waters, the dens-  
38 est oceanic waters, form in the Southern Ocean and fill the global abyssal oceans up to a depth of  
39 about 2500 m (Talley 2013a). They outcrop at the surface only in the Southern Ocean, where they  
40 experience a significant area-integrated buoyancy loss (Abernathey et al. 2016) and are converted  
41 back into lighter waters by mixing with lighter overlying waters, resulting in a diabatic abyssal  
42 overturning circulation of  $O(15 \text{ Sv})$ , where  $1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$ . Non-linearities in the equation of  
43 state of seawater and geothermal heating at the seafloor are thought to play secondary roles in shap-  
44 ing this circulation and will be ignored in the conceptual models described below (Emile-Geay and  
45 Madec 2009; de Lavergne et al. 2016a).

46 Classical theories for the abyssal ocean describe the steady state circulation and stratification of  
47 a flat-bottom ocean forced by uniform turbulent mixing (Stommel 1957; Robinson and Stommel  
48 1959; Stommel and Arons 1959b,a; Munk 1966). These theories remain pedagogically useful,  
49 but are at best qualitative descriptions, as demonstrated for example by the fact that the direction

50 of the flow in the Stommel and Arons (1959b) solution changes sign when a realistic seafloor  
51 slope is introduced (Rhines 1993) and that the Munk (1966) solution does not satisfy the no-  
52 flux boundary condition at the seafloor. The classical view of a uniform mixing-driven upwelling  
53 is further challenged by the observation that turbulent mixing is typically bottom-enhanced over  
54 rough topography (see MacKinnon et al. 2017 for a recent review), reversing the sign of the vertical  
55 flow implied by the interior ocean vertical density balance (Polzin et al. 1997; Ferrari et al. 2016).

56 Since Munk (1966), several approaches have been taken to address the limitations of classical  
57 theories. First, boundary layer theories (Wunsch 1970; Thorpe 1987; Garrett 1990; Thompson  
58 and Johnson 1996) arose to elucidate the local behavior of mixing-induced flow along a sloping  
59 and insulating sea floor. Second, the limitations of the Stommel and Arons (1959b) theory in-  
60 spired a number of extensions to account for baroclinic structure (Kawase 1987; Pedlosky 1992),  
61 non-uniform seafloor depth (Rhines 1993), and/or non-uniform turbulent diffusivities  $\kappa$  (Marotzke  
62 1997; Samelson 1998). Third, the observation of bottom-enhanced mixing motivated the devel-  
63 opment of progressively more sophisticated parameterizations of vertical (or diapycnal) turbu-  
64 lent diffusivities (Bryan and Lewis 1979; St. Laurent and Garrett 2002; Polzin 2009) which have  
65 been subsequently implemented into general circulation models (Huang and Jin 2002; Jayne 2009;  
66 Melet et al. 2016). Fourth, the conundrum of interior downwelling implied by bottom-enhanced  
67 mixing was resolved by applying the watermass transformation framework to a downwelling in-  
68 terior layer of turbulent buoyancy flux divergence and an upwelling bottom boundary layer of  
69 turbulent buoyancy flux convergence, respectively (Ferrari et al. 2016; de Lavergne et al. 2016b;  
70 McDougall and Ferrari 2017). Despite the direct relevance of all of these approaches to the abyssal  
71 circulation, there has been little work done to unify them into a general theory of the abyssal cir-  
72 culation and stratification.

73 Building on the framework introduced by Callies and Ferrari (2018) (hereafter, CF18), we  
74 present a unified prognostic model of the circulation in an abyssal basin forced by bottom-  
75 enhanced mixing along a mid-ocean ridge. We modify the geometry, buoyancy forcing, and initial  
76 condition of the CF18 model to include the effects of a smooth mid-ocean ridge (with the effects  
77 of local roughness parameterized by bottom-enhanced mixing) and of a non-uniform background  
78 stratification on the circulation. Our approach is to formulate the simplest possible model which  
79 captures what we believe to be the key aspects of the problem: 1) the transformation of abyssal  
80 bottom waters into relatively lighter deep waters by bottom-enhanced mixing on the flanks of a  
81 mid-ocean ridge, 2) frictional processes acting on boundary currents, 3) restratification of abyssal  
82 mixing layers by baroclinic turbulence (crudely parameterized as a linear drag on the horizontal  
83 flow), and 4) bottom water formation in the Southern Ocean.

84 The general structure of the abyssal circulation that emerges from the model consists of layered  
85 deep western boundary currents along the western continental slope which are connected by zonal  
86 flows to watermass transformations driven by bottom-enhanced mixing along a mid-ocean ridge,  
87 as schematized in Figure 1. The evolution of the interior stratification and the mixing layer wa-  
88 termass transformations are coupled by slope-normal exchange flows, with the vertically-varying  
89 equilibrium stratification being determined by a combination of the mixing layer dynamics and the  
90 formation of dense waters in the south. Finite net watermass transformations arise ubiquitously  
91 along the flanks of the mid-ocean ridge, supported by vertical variations in the interior stratifi-  
92 cation, such that the crest of the mid-ocean ridge determines the vertical extent of the abyssal  
93 overturning cell, in contrast to a previous constant-stratification interpretation in which finite net  
94 transformations are confined to the base of topographic slopes (CF18).

95 The paper is structured as follows. Section 2 reviews the results of several theories of abyssal  
96 stratification and circulation in the literature. Section 3 presents the formulation of the Planetary

97 Geostrophic Circulation Model (PGCM) used to produce the simulation results presented in the  
98 paper. Section 4 describes the general structure of the abyssal circulation as it emerges in the  
99 PGCM. In Section 5 we use local solutions to the one-dimensional boundary layer equations to  
100 emulate the three-dimensional abyssal circulation in the PGCM. Section 6 describes the spin-up to  
101 equilibrium of the vertical structure of abyssal interior stratification and its influence on watermass  
102 transformations. Section 7 compares watermass transformations in our PGCM simulations with  
103 estimates for the mid-ocean ridges of the Pacific, Atlantic, and Indian Ocean basins. Section 8  
104 compares diagnostic estimates of abyssal upwelling from the watermass transformation framework  
105 with the classic vertical advection-diffusion framework and evaluates the relative contributions of  
106 various physical terms of the watermass transformation. Section 9 discusses the implications of  
107 our results, some key caveats, and some promising future directions.

## 108 **2. Theoretical Background**

### 109 *a. Classical theories of abyssal stratification and circulation*

110 Modern theories of the abyssal circulation begin with a series of papers by Stommel and Arons  
111 (1959b,a). In their theory, the circulation of a homogeneous abyssal layer is fed by high-latitude  
112 sources of abyssal water (diabatic downwelling) and driven by a uniformly-distributed sink (di-  
113 abatic upwelling) of abyssal water. A uniform upwelling across the base of the thermocline is  
114 prescribed, inspired by the thermocline-thermohaline theory of Robinson and Stommel (1959).  
115 Munk (1966) further simplifies the Robinson and Stommel (1959) balance by restricting his atten-  
116 tion to the deep ocean (i.e. below the thermocline) and by considering only vertical advection and  
117 diffusion,

$$u^z \partial_z b = \partial_z (\kappa \partial_z b), \quad (1)$$

118 where  $b$  is buoyancy,  $u^z$  is a uniform vertical velocity,  $\kappa$  is a uniform turbulent diffusivity. The  
 119 Munk formulation allows exponential solutions which can be fit to the observed temperature pro-  
 120 files and combined with fits of an advection-diffusion-decay equation to radiocarbon profiles to  
 121 yield the canonical estimate of deep ocean mixing  $\kappa \simeq 10^{-4} \text{ m}^2\text{s}^{-1}$  for a uniform upwelling of  
 122  $u^z = 1.4 \times 10^{-7} \text{ m/s}$ .

123 The horizontal abyssal circulation associated with the upwelling is described by Stommel and  
 124 Arons (1959b,a): interior flow is geostrophically-balanced and its meridional component  $u^y$  is  
 125 driven by vortex stretching, as shown by the vertically-integrated planetary-geostrophic vorticity  
 126 balance

$$\beta U^y = f \frac{u_0^z}{H}, \quad (2)$$

127 where  $H$  is the thickness of the abyssal layer,  $u_0^z > 0$  is the upwelling across the base of the  
 128 thermocline,  $f$  is the Coriolis parameter,  $\beta > 0$  is the meridional gradient of the Coriolis parameter,  
 129 and the vertically-integrated flow  $U^y$  is thus poleward in both hemispheres (see Pedlosky 1996  
 130 for an elucidating derivation). Inspired by the success of analogous theories for the wind-driven  
 131 gyre circulation (Stommel 1948), Stommel and Arons (1959b,a) suppose the existence of a deep  
 132 western boundary current in which frictional effects allow the current to deviate from geostrophy  
 133 and return the interior flow such that the abyss conserves mass.

#### 134 *b. Turning ocean mixing upside down*

135 The Stommel and Arons (1959b,a) and Munk (1966) theories rely on the existence of a uniform  
 136 turbulent diffusivity  $\kappa \simeq 10^{-4} \text{ m}^2\text{s}^{-1}$ , roughly an order of magnitude larger than the interior ocean  
 137 mixing inferred from observations (Gregg 1989; Ledwell et al. 1993). While sufficiently vigorous  
 138 mixing was eventually discovered deeper in the ocean near rough seafloor topography (Polzin  
 139 et al. 1997; Ledwell et al. 2000; Sheen et al. 2013), the abyssal mixing problem only became

140 more complicated: applying the vertical advection-diffusion balance (eq.1) point-wise to mixing  
 141 profiles  $\kappa(z)\partial_z b$  that increase with depth implies diapycnal *downwelling*

$$u^z = (\partial_z b)^{-1} \partial_z (\kappa \partial_z b) < 0, \quad (3)$$

142 in contrast to the diapycnal *upwelling* required to balance diapycnal downwelling at high lati-  
 143 tudes<sup>1</sup>!

144 This apparent conundrum is resolved by considering the insulating boundary condition at a  
 145 sloping seafloor, which causes buoyancy convergence and hence diapycnal upwelling in a thin  
 146 bottom boundary layer (Polzin et al. 1997; Ferrari et al. 2016; de Lavergne et al. 2016b). In this  
 147 framework, the abyssal overturning is the net effect of downwelling driven by bottom-enhanced  
 148 mixing in a stratified mixing layer and upwelling driven by buoyancy convergence in a bottom  
 149 boundary layer, which we collectively refer to as abyssal mixing layers (CF18).

### 150 *c. A puzzling constraint from boundary layer theory*

151 Bottom boundary layer theory (see review of Garrett et al. 1993) is a useful dynamical approach  
 152 to the problem of flow driven by near-boundary mixing on a slope, which exerts a strong control on  
 153 the basin-scale abyssal circulation (CF18). Following Thorpe (1987), who built on the approaches  
 154 of Wunsch (1970) and Phillips (1970), we rotate the Boussinesq equations into slope coordinates  
 155 and assume the flow depends only on the slope-normal coordinate  $z'$ , which gives the simplified  
 156 buoyancy equation (see derivation of full equation set in Section 5a):

$$\partial_t b' + u^{x'} N_0^2 \sin \theta = \partial_{z'} [\kappa (N_0^2 \cos \theta + \partial_{z'} b')] \quad (4)$$

157 where  $u^{x'}$  is the up-slope velocity,  $\theta$  the slope angle,  $\kappa = \kappa(z')$  the turbulent diffusivity, and we  
 158 decompose the buoyancy field  $b(x, y, z, t) = N_0^2 z + b'(x, y, z, t)$  into a background corresponding to

---

<sup>1</sup>While the sign of the vertical velocity changes, we note that  $\partial_z u^z > 0$  and thus the interior geostrophic flow driven by vortex stretching is still of the same sign as in the Stommel-Arons solution.

159 a constant stratification  $N_0^2$  and a buoyancy anomaly  $b' = b'(z')$ . The boundary conditions are a no-  
 160 flux condition  $\partial_{z'} b = \partial_{z'} b' + N_0^2 \cos \theta = 0$  at the seafloor  $z' = 0$  and decay conditions  $\partial_{z'} u^{x'}, \partial_{z'} b' \rightarrow 0$   
 161 as  $z' \rightarrow \infty$ . At steady state, the boundary layer equation for the buoyancy anomaly (eq. 4) can be  
 162 integrated from  $z' = 0$  to  $z' \rightarrow \infty$ , which yields

$$\Psi_{\text{bg}} \equiv \kappa_{\text{bg}} \cot \theta, \quad (5)$$

163 for the net up-slope transport per unit length  $\Psi_{\text{bg}} = \int_0^\infty u^{x'} dz'$ , where  $\kappa_{\text{bg}} \equiv \kappa(z \rightarrow \infty)$  is the  
 164 background diffusivity. The simplicity of this integral constraint is surprising: the net up-slope  
 165 transport depends only on the background turbulent diffusivity  $\kappa_{\text{bg}}$  and the slope angle  $\theta$ , and is  
 166 independent of other environmental parameters which might be expected to influence diapycnal  
 167 transport, such as frictional parameters, the background stratification  $N_0^2$ , the Coriolis parameter  
 168  $f$ , and the vertical structure of the turbulent diffusivity  $\kappa(z)$ .

169 Integrating the prediction  $\Psi_{\text{bg}}$  for the diapycnal transport per unit length along the perimeter  
 170  $L_{\text{global}} \simeq 10^8$  m of the global mid-ocean ridge system (Callies 2018) for a typical ridge slope  
 171  $\tan(\theta) = 2 \times 10^{-3}$  and a background diffusivity of  $\kappa_{\text{bg}} \simeq 10^{-5} \text{ m}^2 \text{ s}^{-1}$  produces a global mixing-  
 172 driven diapycnal overturning transport of  $L_{\text{global}} \kappa_{\text{bg}} \cot \theta \simeq 0.5$  Sv, more than an order of magni-  
 173 tude smaller than the observed abyssal diapycnal overturning transport of roughly 15 Sv (Lumpkin  
 174 and Speer 2007).

175 CF18 resolve this conundrum by using the magnitude of the upwelling-downwelling ‘dipole’  
 176 from boundary layer theory as a prediction for the net watermass transformation, since at the  
 177 base of topographic slopes the flows in and out of the boundary layers occur at different density  
 178 classes and thus drive a diabatic overturning. They find that the strictly upwelling transport in the  
 179 bottom boundary layer accurately predicts the scaling of the maximum net diapycnal overturning

180 transport, although the predicted overturning is unrealistically confined to the base of topographic  
181 slopes where the constraints from one-dimensional boundary layer theory break down.

#### 182 *d. Boundary-interior exchange*

183 The integral constraint  $\Psi_{\text{bg}} \equiv \kappa_{\text{bg}} \cot \theta$  (eq. 5) relies on the assumption of constant background  
184 stratification  $N_0^2$  and slope angle  $\theta$ . By construction, none of the other terms are assumed to vary in  
185 the plane of the slope  $(x', y')$  either; it follows that there are no cross-slope convergences  $\partial_{x'} u^{x'} = 0$   
186 and hence no slope-normal exchange between the abyssal mixing layers and the interior,  $u^{z'} = 0$   
187 (Wunsch 1970).

188 With a vertically varying stratification  $N^2(z)$ , however, variations in the buoyancy gradient  
189 project onto the cross-slope direction  $x' = x \cos \theta + z \sin \theta$ , introducing a second dimension to the  
190 problem (e.g. Phillips et al. 1986; Salmun et al. 1991) and permitting both slope-normal exchange  
191 flows  $u^{z'} \neq 0$  and a net diapycnal transport  $\Psi_{\infty} \equiv \int_0^{\infty} u^{x'} dz' \neq \Psi_{\text{bg}}$ . Heterogeneities can also arise  
192 due to cross-slope variations in the turbulent diffusivity  $\kappa(x, y)$  or the slope angle  $\theta(x, y)$  (Dell and  
193 Pratt 2015), and have been argued to contribute significantly to oceanic watermass transformations  
194 (McDougall and Ferrari 2017; de Lavergne et al. 2017; Holmes et al. 2018). These additional het-  
195 erogeneities are both kept relatively small by construction in our idealized model configuration to  
196 keep the focus on the effects of variations in the basin stratification.

#### 197 *e. Dynamics controlling the interior abyssal stratification*

198 The abyssal stratification is thought to be controlled by the combined effects of 1) diapycnal mix-  
199 ing in ocean basins; and 2) the competing effects of winds and mesoscale eddies in setting the slope  
200 of isopycnals in the Southern Ocean. Diapycnal mixing maintains the stable stratification of the  
201 abyssal ocean by effectively diffusing buoyancy downwards, transforming dense abyssal waters

202 into lighter deep waters (Munk 1966). This vertical advection-diffusion model is an incomplete  
203 model of the abyssal stratification, however, as it omits the complementary process which closes  
204 the overturning circulation by transforming light deep waters into denser abyssal waters. Munk  
205 and Wunsch (1998) consider a heuristic correction to Munk (1966)'s vertical advection-diffusion  
206 equation for the effect of horizontal advection from regions of high mixing (or homogenization  
207 by convection), which acts to restratify regions of weak mixing. A breakthrough in understanding  
208 the abyssal stratification was the development of quasi-adiabatic theories of Southern Ocean cir-  
209 culation. In these theories, deep waters are upwelled adiabatically along sloping isopycnals in the  
210 Southern Ocean, are transformed into abyssal waters in the Southern Ocean mixed layer by a neg-  
211 ative surface buoyancy flux, and return to the abyss adiabatically along isopycnals (Marshall and  
212 Speer 2012, and references therein). The Southern Ocean isopycnal slope is determined by a bal-  
213 ance between wind stress and stirring by mesoscale eddies, which steepen and flatten isopycnals,  
214 respectively (Marshall and Radko 2003).

215 Building on these two independent theories, Nikurashin and Vallis (2011) develop an idealized  
216 model which couples quasi-adiabatic Southern Ocean dynamics to a diabatic abyssal ocean basin  
217 and predicts the abyssal stratification and circulation, given only surface boundary conditions and  
218 mixing coefficients. For moderate diapycnal mixing of  $10^{-5} \text{ m}^2\text{s}^{-1} < \kappa < 10^{-3} \text{ m}^2\text{s}^{-1}$ , a regime  
219 applicable to both the Ocean and the model described here, the Nikurashin and Vallis (2011) model  
220 predicts that the interior abyssal stratification depends both on winds and eddies in the Southern  
221 Ocean and diapycnal mixing in the basin.

222 A promising aspect of zonally-integrated models of the meridional overturning circulation (e.g  
223 Nikurashin et al. 2012; Thompson et al. 2016) is that they accurately reproduce the overturning  
224 and stratification exhibited by idealized “box”-geometry general circulation models. The emerging  
225 view, however, is that the abyssal circulation of the ocean is controlled by mixing layer flows

226 along sloping boundaries and thus that the commonly-used “box” geometry models may be a  
 227 misleading point of reference for theories of the abyssal stratification and circulation (Ferrari et al.  
 228 2016). Building on CF18, we describe the formulation of an improved idealized general circulation  
 229 model in a “bowl + ridge” geometry which accommodates the recent revisions to our theoretical  
 230 understanding of the abyssal ocean circulation.

### 231 **3. Planetary Geostrophic Circulation Model (PGCM)**

232 The numerical model used here is the Planetary Geostrophic Circulation Model (PGCM) devel-  
 233 oped by CF18 to study how bottom-enhanced mixing on slopes drives an abyssal circulation. We  
 234 describe the key elements of our PGCM configuration below, which closely follows the exposi-  
 235 tion of CF18. The main differences between the present study and CF18 are the inclusion of the  
 236 mid-ocean ridge, the localization of vigorous bottom-enhanced mixing to a mid-ocean ridge, and  
 237 the generalization to vertically-varying interior stratifications. Readers familiar with the methods  
 238 of CF18 can skip Section 3 and simply consult Figure 2, which summarizes our changes to the  
 239 configuration.

#### 240 *a. Equations*

241 The model solves the Navier-Stokes equations under the Boussinesq and planetary-scale  
 242 geostrophic approximations, with parameterizations for the frictional and diabatic effects of unre-  
 243 solved processes, given by

$$f\mathbf{z} \times \mathbf{u} = -\nabla p + b\mathbf{z} - r(u^x\mathbf{x} + u^y\mathbf{y}), \quad (6)$$

$$\nabla \cdot \mathbf{u} = 0, \text{ and} \quad (7)$$

$$\frac{\partial b}{\partial t} + \mathbf{u} \cdot \nabla b = \nabla \cdot (\kappa \nabla b) - \lambda(y)(b - B(z)), \quad (8)$$

244 where  $t$  is time;  $\mathbf{x}, \mathbf{y}, \mathbf{z}$  are unit vectors pointing east, north, and up, respectively;  $f = \beta y$  is the lin-  
 245 earized Coriolis parameter ( $\beta$ -plane approximation);  $\mathbf{u} = (u^x, u^y, u^z)$  is the velocity vector;  $p$  is the  
 246 pressure divided by a reference density;  $b$  is the buoyancy;  $r$  is a frictional parameter;  $\kappa = \kappa(x, y, z)$   
 247 is a spatially-dependent turbulent diffusivity; and  $\lambda = \lambda(y)$  is a meridionally-varying restoring rate  
 248 (see Section 3c). The system of equations (6) - (8), with appropriate initial and boundary condi-  
 249 tions, yields a self-consistent and prognostic model of abyssal circulation and stratification.

250 The Boussinesq approximation filters out acoustic waves while the planetary-geostrophic ap-  
 251 proximation filters out gravity waves and geostrophic turbulence. The resulting planetary-  
 252 geostrophic equations are appropriate for basin-scale oceanic circulations and are typically used  
 253 for idealized studies of the abyssal circulation (e.g Pedlosky 1996, and references therein) and  
 254 intermediate-complexity earth system models (e.g. Holden et al. 2016). While it is computation-  
 255 ally and conceptually useful that the planetary-geostrophic equations filter out the effects of fast  
 256 waves and turbulence, the turbulent fluxes of these relatively small-scale flows are thought to  
 257 have leading order effects on abyssal mixing layers. We include their qualitative effects in the  
 258 planetary-geostrophic formulation by way of two idealized parameterizations.

259 First, to include the effects of turbulent mixing produced by the local breaking of internal waves  
 260 generated by flow over rough topography, we introduce a term for the turbulent buoyancy flux  
 261 convergence  $\nabla \cdot (\kappa \nabla b)$  to the buoyancy equation (e.g. as in St. Laurent and Garrett 2002). The  
 262 imposed spatially-dependent turbulent diffusivity  $\kappa(x, y, z)$  approximates the leading-order spatial  
 263 structure described by observational estimates<sup>2</sup> (e.g. Polzin et al. 1997; Waterhouse et al. 2014)  
 264 and is described in detail in Section 3c.

---

<sup>2</sup>Quantitatively similar profiles of turbulent kinetic energy dissipation are reproduced in simulations of internal wave turbulence above rough topography, wherein energy from a geostrophic mean flow (Nikurashin and Ferrari 2009) or the barotropic tide (Nikurashin and Legg 2011) is converted into unstable high-mode internal waves via a cascade of wave-wave interactions.

265 Second, to include the qualitative effects of isopycnal mixing by baroclinic turbulence in re-  
 266 stratifying the abyssal mixing layers (Callies 2018) and in thickening western boundary currents  
 267 (e.g. Stommel 1948), we introduce a dissipative term to the momentum equation. Greatbatch  
 268 and Lamb (1990) show that introducing vertical momentum diffusion  $\partial_z (v_{\text{eddy}} \partial_z \mathbf{u})$  to the plane-  
 269 tary geostrophic equations with an eddy viscosity  $v_{\text{eddy}} = \kappa_{\text{GM}} f^2 / N^2$  is equivalent to introducing  
 270 isopycnal diffusion of potential vorticity with an effective isopycnal diffusivity of  $\kappa_{\text{GM}}$  (Gent and  
 271 McWilliams 1990). Following Salmon (1992), we simplify the dynamics further by using a linear  
 272 friction term (Rayleigh drag),  $-r(u^x \mathbf{x} + u^y \mathbf{y})$  and scale the frictional parameter  $r$  according to the  
 273 Greatbatch and Lamb (1990) parameterization,

$$r = \kappa_{\text{GM}} \frac{f^2}{\delta^2 N^2} \approx 1.2 \times 10^{-5} \text{ s}^{-1}, \quad (9)$$

274 where we choose  $\delta = 400$  m to be roughly the thickness of the abyssal mixing layers observed  
 275 in the Brazil Basin (Callies 2018); typical abyssal mixing layer values of  $f = 5 \times 10^{-5} \text{ s}^{-1}$  and  
 276  $N^2 = 5 \times 10^{-7} \text{ s}^{-1}$ ; and in the absence of observational or theoretical constraints assume  $\kappa_{\text{GM}} =$   
 277  $100 \text{ m}^2 \text{ s}^{-1}$ , which yields a value  $v_{\text{eddy}} = 0.5 \text{ m}^2 \text{ s}^{-1}$  similar to the value  $v_{\text{eddy}} = \sigma \kappa_{\text{bot}} = 0.4$   
 278  $\text{m}^2 \text{ s}^{-1}$  proposed by Callies (2018); Holmes et al. (2019), where  $\sigma$  is the turbulent Prandtl number.  
 279 We use a constant  $r$  since the parameterization is meant to be a crude placeholder for boundary  
 280 layer restratification. To our relief, supplementary sensitivity experiments showed that watermass  
 281 transformations and the boundary layer structure are relatively insensitive to the friction parameter  
 282  $r$ , in agreement with CF18. The linear drag parameter is small enough that the frictional terms  
 283 are negligible in the interior where the flow is approximately geostrophic and are important only  
 284 in near-boundary flows (both the deep western boundary currents and the abyssal mixing layers  
 285 along the mid-ocean ridge) where the horizontal velocities are large (Salmon 1992, CF18). The  
 286 choice of  $r = 1.2 \times 10^{-5} \text{ s}^{-1}$  gives a non-dimensional value  $\hat{r} = \frac{r}{\beta L} = 0.1$  such that the width of

287 the Stommel and Arons (1959b,a) deep western boundary currents is one-tenth the domain width  
288 (see Section 3d).

289 *b. Geometry and boundary conditions*

290 We configure the PGCM to approximate the leading-order structure of a typical cross-  
291 hemispheric abyssal ocean basin with a rectangular basin of zonal width  $L = 3000$  km and merid-  
292 ional length  $2L = 6000$  km. Our idealized basin contains a mid-ocean ridge caused by seafloor  
293 spreading in the middle and is bounded in the west, east, and north by continental slopes (Figure  
294 2a). Although the southern region in our configuration ( $y < -L/2 = -3000$  km) is also zonally  
295 bounded, it should be thought of as a Southern Ocean-like sponge layer. In this southern region,  
296 the transformation of deep waters into bottom waters arising from complex circumpolar channel  
297 dynamics (e.g. as described in Marshall and Speer 2012) are parameterized by an idealized buoy-  
298 ancy restoring forcing which pins the buoyancy field to a reference vertical profile (described in  
299 detail in the next Section 3c). The model extends from  $z = -2500$  m at the upper boundary to a  
300 maximum depth of  $z = -5000$  m and should be interpreted as representing only the diabatic lower  
301 cell of the meridional overturning circulation. The idealized configuration can be thought to apply  
302 locally to the Atlantic, Pacific, and Indian Ocean basins below  $z = -2500$  m, which in the present  
303 climate are all bounded by topography in the west, east, and north and have roughly meridionally-  
304 aligned mid-ocean ridges (e.g. those highlighted in Figure 12). The idealized continental slopes  
305 are half-Gaussian and the mid-ocean ridge is Gaussian in the zonal direction and tapers down  
306 to zero meridionally in the southern restoring region to allow unconstrained zonal flows to close  
307 the circulation of interest in the diffusively-forced basin to the north. The characteristic seafloor  
308 slopes of roughly  $\tan(\theta_{ridge}) \simeq 2 \times 10^{-3}$  for the mid-ocean ridge and  $\tan(\theta_{cont.}) \simeq 4 \times 10^{-3}$  for the  
309 continental slope are inspired by the South Atlantic, where the abyssal mixing layers and large-

310 scale abyssal circulation are best constrained by existing observations (Polzin et al. 1997; Ledwell  
 311 et al. 2000; St. Laurent et al. 2001; Thurnherr et al. 2005). The PGCM is bounded from above by  
 312 assuming isopycnals are flat, i.e.  $b = 0$  at  $z = -2500$  m, which is approximately valid in all basins  
 313 north of the Southern Ocean (Talley 2007; Koltermann et al. 2011; Talley 2013b). The PGCM  
 314 is bounded from below by an insulating seafloor,  $\mathbf{n} \cdot \nabla b = 0$  at  $z = -d(x, y)$ , where  $d(x, y)$  is the  
 315 seafloor depth and  $\mathbf{n}$  is the unit vector normal to the boundary.

### 316 *c. Buoyancy forcing*

317 The abyssal circulation in our model is forced by two competing diabatic terms in the buoy-  
 318 ancy equation: minus the divergence of the turbulent buoyancy flux  $-\nabla \cdot (-\kappa \nabla b)$ , which has a  
 319 positive integral contribution (diapycnal upwelling); and restoring to a reference buoyancy pro-  
 320 file  $-\lambda(b - B)$ , which must necessarily have a negative integral contribution (diapycnal down-  
 321 welling). Available potential energy is produced by parameterized turbulent mixing and converted  
 322 into kinetic energy via the buoyancy production term  $u^z b$  to drive a planetary-geostrophic abyssal  
 323 circulation and balance the available potential energy loss due to restoring.

#### 324 *(i) Turbulent mixing*

325 The prescribed turbulent diffusivity  $\kappa = \kappa(x, y, z)$  is everywhere bottom-enhanced with a contri-  
 326 bution equal to  $\kappa_{\text{bot}} \exp\{-(z + d)/h\}$  over the mid-ocean ridge, where we choose  $\kappa_{\text{bot}} = 5 \times 10^{-3}$   
 327  $\text{m}^2\text{s}^{-1}$  and  $h = 250$  m to roughly match observations in the Brazil Basin (Figure 11). The bottom-  
 328 enhanced contribution to  $\kappa$  is reduced by a factor of 20 to  $\frac{\kappa_{\text{bot}}}{20} \exp\{-(z + d)/h\}$  over the con-  
 329 tinental slopes to reflect the observed weakness of local wave-driven turbulence over smooth  
 330 continental slopes (Figure 11 and Polzin et al. 1997). A uniform weak background diffusivity  
 331  $\kappa_{\text{bg}} = \frac{\kappa_{\text{bot}}}{200} = 2.5 \times 10^{-5} \text{m}^2\text{s}^{-1}$  is added to stabilize the numerical solution above the continental

332 slopes, which yields a total diffusivity distribution

$$\kappa(x, y, z) = \kappa_{bg} + \begin{cases} \kappa_{bot} \exp\{-(z + d(x, y))/h\}, & \text{if } L/2 < x < 3L/2 \text{ (mid-ocean ridge)} \\ \frac{\kappa_{bot}}{20} \exp\{-(z + d(x, y))/h\}, & \text{else (continental slopes),} \end{cases} \quad (10)$$

333 with a smoothing function applied over a horizontal distance of  $L/10$  near the transitions at  $x = L/2$   
 334 and  $x = 3L/2$ . The net effect of this prescribed mixing is to power a diabatic upwelling along the  
 335 mid-ocean ridge, where mixing is vigorous.

336 *(ii) Buoyancy restoring in the southern restoring region*

337 The prescribed restoring rate  $\lambda$  is has a meridional dependence

$$\lambda(y) = \lambda_0 \left[ 0.5 \left( 1 - \tanh \left( \frac{y + L/2}{10L} \right) \right) \right] \quad (11)$$

338 which is equal to  $\lambda_0 \simeq (10 \text{ years})^{-1}$  in the southern restoring region and vanishes rapidly north-  
 339 wards,  $\lambda \rightarrow 0$  as  $y > -L/2$ . The prescribed restoring rate is chosen based on the baroclinic ad-  
 340 justment timescale given by a lateral diffusive timescale  $\tau_{SO} = L_{SO}^2 / \kappa_{GM} = \frac{(10^6 \text{ m})^2}{3000 \text{ m}^2 \text{ s}^{-1}} \simeq 10 \text{ years}$ ,  
 341 determined for an isopycnal diffusivity  $\kappa_{GM} \simeq 3000 \text{ m}^2 \text{ s}^{-1}$  (Abernathey et al. 2013), and a South-  
 342 ern Ocean of width  $L_{SO} \simeq 1000 \text{ km}$ . This restoring rate is much faster than the vertical diffusive  
 343 timescale which spins up the overturning circulation  $\tau_{mix} = H^2 / \bar{\kappa} \simeq 1000 \text{ years}$ , where  $H = 2500$   
 344 m is the maximum thickness of the abyssal ocean and  $\bar{\kappa} \simeq 10^{-4} \text{ m}^2 \text{ s}^{-1}$  is the volume-weighted  
 345 mean diffusivity in the basin. Thus, the stratification in the southern restoring region does not devi-  
 346 ate much from the prescribed profile (see Figure 7). The net effect of this parameterized buoyancy  
 347 forcing in the southern restoring region is to transform deep waters into bottom waters (diabatic  
 348 downwelling) to balance the transformation of bottom waters into deep waters (diabatic upwelling)  
 349 driven by mixing along the mid-ocean ridge in the basin to the north. In contrast to CF18, we allow  
 350 the reference buoyancy field  $B(z)$  to have vertically-varying stratification  $\partial_z B = N^2(z)$ , complicat-

351 ing the interpretation of the solution in terms of one-dimensional boundary layer dynamics which  
 352 require a constant interior stratification  $N_0^2$ .

353 *d. Dimensional parameters and scaling*

354 While the PGCM is discussed dimensional terms, the PGCM is formulated and implemented  
 355 non-dimensionally. The following dimensional scales,

$$\begin{aligned}
 L &= 6000 \text{ km} && \text{(basin width),} \\
 H &= 2500 \text{ m,} && \text{(abyssal ocean vertical extent),} \\
 \beta &= 2 \times 10^{-11} \text{ m}^{-1} \text{ s}^{-1}, && \text{(meridional gradient of Coriolis parameter),} \\
 N^2 &= 1.5 \times 10^{-6} \text{ s}^{-2}, && \text{(reference stratification at } z = -2500 \text{ m),} \\
 \kappa_{bot} &= 5 \times 10^{-3} \text{ m}^2 \text{ s}^{-1}, && \text{(diffusivity at the mid-ocean ridge seafloor),} \\
 r &= 1.2 \times 10^{-5} \text{ s}^{-1}, && \text{(frictional parameter),}
 \end{aligned}$$

356 are used to non-dimensionalize the system, with the coordinate transformation

$$x = L\hat{x}, \quad y = L\hat{y}, \quad z = H\hat{z} \quad (12)$$

357 and the substitutions

$$t = \frac{\beta L^3}{N^2 H^2} \hat{t}, \quad b = N^2 H \hat{b}, \quad p = N^2 H^2 \hat{p}, \quad (13)$$

$$u^x = \frac{N^2 H^2}{\beta L^2} \hat{u}^{\hat{x}}, \quad u^y = \frac{N^2 H^2}{\beta L^2} \hat{u}^{\hat{y}}, \quad u^z = \frac{N^2 H^3}{\beta L^3} \hat{u}^{\hat{z}}. \quad (14)$$

358 For reference, the non-dimensional time  $\hat{t} = 1$  corresponds to  $t = \tau \simeq 10$  years, where  $\tau \equiv$

359  $\beta L^3 / N^2 H^2$ . While the basin scale circulation takes a long time  $\tau_{\text{mix}} = H^2 / \bar{\kappa} \simeq 1000$  years  $\gg \tau$  to

360 spin up, the abyssal mixing layers are spun up on a fast timescale  $\tau_{\text{BL}} = q^{-2} / \kappa_{\text{bot}} \simeq 1$  year  $\ll \tau$ ,

361 where

$$q^{-1} = \sqrt{\frac{\kappa_{\text{bot}}(f^2 + r^2)}{rN^2 \tan^2 \theta}} \simeq 400 \text{ m} \quad (15)$$

362 is the thickness of the mixing layer predicted by 1D theory (CF18),  $\kappa_{\text{bot}} = 5 \times 10^{-3} \text{ m}^2/\text{s}$  is the

363 diffusivity at the seafloor, and  $f = \beta L / 2$  as a representative value of the Coriolis parameter.

364 The non-dimensionalized equations (see CF18) depend only on the non-dimensional parameters

$$\hat{\alpha} = \frac{H}{L}, \quad \hat{\kappa} = \frac{\kappa\beta L^3}{N^2 H^4}, \quad \hat{r} = \frac{r}{\beta L}, \quad (16)$$

365 where  $\hat{\alpha}$  is the aspect ratio of the basin;  $\hat{\kappa} = \tau/\tau_{\text{mix}}$  is the ratio of the cross-basin propagation  
 366 timescale of long Rossby waves (with  $f = \beta L$ )

$$\tau \equiv L/c_g = L/\frac{\beta L^{-2}}{(NH/f)^2} = \frac{\beta L^3}{N^2 H^2}, \quad (17)$$

367 to the diffusive spin-up timescale  $\tau_{\text{mix}} \equiv H^2/\bar{\kappa}$ .  $\hat{r}$  is the ratio of the Stommel (1948) western  
 368 boundary layer width  $r/\beta$  to the basin width  $L$ . Since the prescribed  $\kappa$  is spatially-dependent,  
 369 the non-dimensional diffusivity  $\hat{\kappa}$  inherits its spatial dependence in the numerical implementa-  
 370 tion. Scaling  $\kappa$  by using the volume-weighted average value  $\bar{\kappa}$  in  $\tau_{\text{mix}}$  gives  $\hat{\kappa} = \tau/\tau_{\text{mix}} \simeq 0.01$ .  
 371 Because the imposed turbulent diffusivity is isotropic, the small aspect ratio  $\hat{\alpha} \sim 5 \times 10^{-4}$  re-  
 372 sults in a non-dimensionalized horizontal diffusivity many orders of magnitude smaller than the  
 373 non-dimensionalized vertical diffusivity, which is difficult to implement numerically. Instead,  
 374 we artificially increase the horizontal diffusivity for numerical stability by increasing the as-  
 375 pect ratio parameter to  $\hat{\alpha} = 0.2$ . This parameter only enters in the horizontal diffusion term  
 376  $\hat{\alpha}^2 [\partial_{\hat{x}} (\hat{\kappa} \partial_{\hat{x}} \hat{b}) + \partial_{\hat{y}} (\hat{\kappa} \partial_{\hat{y}} \hat{b})]$  (CF18) and remains small  $\hat{\alpha} \ll 1$  such that it does not qualitatively  
 377 affect the results presented here, as evidenced by the negligible role of horizontal buoyancy fluxes  
 378 in the watermass transformations (Figure 5).

### 379 *e. Numerical implementation*

380 The model is formulated in terrain-following coordinates to accurately resolve the thin mixing-  
 381 driving flows along the sloped bottom boundary. The numerical implementation is described in  
 382 CF18. The Julia (Bezanson et al. 2017) implementation is available at <https://github.com/>

383 joernc/pgcm. The input files, output files, and post-processing notebooks necessary to replicate  
384 the study are available at <https://github.com/hdrake/AbyssalFlow> (Drake 2020).

#### 385 **4. Abyssal Circulation Controlled By Mixing Layer Dynamics**

386 We begin by describing the general structure of the abyssal circulation at equilibrium in the  
387 PGCM, i.e. at  $\hat{t} = 50$  or  $t \simeq 500$  years  $\simeq \tau_{\text{mix}}$ , when buoyancy tendencies have become very small  
388 (Figure 7a). The stratification in the PGCM solution presented in this section is restored to an  
389 exponential profile with a decay scale of  $\delta = 1000$  m (solid red dashed line in Figure 2), which  
390 exhibits vertical variations of similar magnitude to those observed in the Southern Ocean (black  
391 solid line). This is arguably our most “realistic simulation” of the abyssal ocean and hereafter we  
392 refer to it as PGCM-REAL.

##### 393 *a. Abyssal Mixing Layers and Deep Western Boundary Currents*

394 Figure 3 (a-c) shows the three Cartesian components of the abyssal flow field along a zonal sec-  
395 tion 3000 km north of the equator. In the abyssal mixing layers spanning both flanks of the mid-  
396 ocean ridge, buoyancy surfaces plunge to intersect the seafloor at a right angle (visually distorted  
397 by the aspect ratio) to satisfy the no-flux boundary condition. As expected from 1D theory (CF18),  
398 the boundary flows are thicker and stronger over the mid-ocean ridge where mixing is strong than  
399 over the continental slopes where mixing is weak. In the bottom boundary layer (BBL), plung-  
400 ing buoyancy surfaces drive frictionally-balanced upwelling (Figure 3c) and frictional-geostrophic  
401 flow opposite the direction of Kelvin wave propagation (Figure 3b), i.e. anti-cyclonic in the north-  
402 ern hemisphere. In the stratified mixing layer (SML) just above the BBL, buoyancy surfaces are  
403 at leading order flat and the bottom-enhanced mixing drives downwelling (Figure 3c), as expected  
404 from the vertical advection-diffusion balance (eq. 3) reviewed in Section 2.

405 A net residual diapycnal upwelling in the Northern Hemisphere can be inferred from the merid-  
406 ional flow field at the equator: dense bottom waters flow into the northern hemisphere and rela-  
407 tively lighter deep waters flow out (Figure 3e). Since the Coriolis force vanishes at the equator, the  
408 buoyant force associated with the bending of buoyancy surfaces to satisfy the bottom-boundary  
409 condition can only be balanced by a cross-slope frictional flow (Figure 3d,f) and any along-slope  
410 flow associated with the abyssal mixing layers vanishes (compare Figure 3e to Figure 3b). The  
411 only meridional flow are Stommel (1948)-like deep western boundary currents (DWBC) along the  
412 continental slope on the western side of the domain and the eastern flank of the ridge (Figure 3e).  
413 In this particular configuration, a southward-flowing DWBC develops on the eastern flank of the  
414 ridge near its crest and is much weaker than the DWBC on the western continental slope. The  
415 southward DWBC on the ridge is relatively intensified in simulations with a taller ridge.

#### 416 *b. Depth-integrated and Overturning Circulations*

417 The global abyssal circulation is more intuitively visualized by considering the three Cartesian  
418 streamfunctions that describe the flow, which we compute by integrating the  $u^x$ ,  $u^y$ , and  $u^z$  veloc-  
419 ities in  $x$ ,  $y$ , and  $z$ , respectively<sup>3</sup> (Figure 4). Figure 4b shows the familiar streamfunction for the  
420 meridional overturning circulation (MOC) in the  $y$ - $z$  plane, which should be thought of as corre-  
421 sponding to the lower-cell of the global MOC. This circulation has a strength of about 1.6 Sv at  
422 the equator, with water 1) downwelling diabatically in the southern restoring region, 2) flowing  
423 northwards to fill the abyssal depths, 3) gradually upwelling along the length of the basin, and 4)  
424 returning to the southern restoring region to close the circulation. We note in particular that the

---

<sup>3</sup>Integrating the continuity equation in  $\frac{\partial u^x}{\partial x} + \frac{\partial u^y}{\partial y} + \frac{\partial u^z}{\partial z} = 0$  along any of the three directions  $x$ ,  $y$ , or  $z$  and imposing the no-normal flow boundary condition yields an equation of the form  $\int \left( \frac{\partial u^{x_1}}{\partial x_1} + \frac{\partial u^{x_2}}{\partial x_2} + \frac{\partial u^{x_3}}{\partial x_3} \right) dx_3 = \frac{\partial U^{x_1}}{\partial x_1} + \frac{\partial U^{x_2}}{\partial x_2} = 0$ , where  $x_1, x_2, x_3$  are permutations of  $x, y, z$ ,  $U^{x_1} = \int u^{x_1} dx_3$  and  $U^{x_2} = \int u^{x_2} dx_3$ . The resulting non-divergent flow field can then be expressed as a streamfunction  $\psi_3$  defined by  $\mathbf{U} = U^{x_1} \mathbf{x}_1 + U^{x_2} \mathbf{x}_2 = (-\nabla \times \psi_3 \mathbf{x}_3)$ .

425 MOC extends all the way from the ocean seafloor to the top of the mid-ocean ridge, in contrast  
426 to the MOC in the CF18 framework, in which significant overturning is confined to the base of  
427 topographic slopes (see Section 6c for a discussion on the role of the ridge height in setting the  
428 vertical extent of the MOC).

429 The up- and down-welling in the abyssal mixing layers is evident in the zonal overturning  
430 streamfunction in the  $x$ - $z$  plane, which shows upwelling in a thin BBL and broader downwelling  
431 in the SML above (Figure 4c). The upwelling in bottom boundary layers is confined to the two  
432 flanks of the mid-ocean ridge, where mixing is vigorous and bottom-enhanced, and is negligible  
433 over the weakly-mixed continental slopes. In this case, the upwelling and downwelling transports  
434 are equal and opposite in strength, i.e. the circulation closes, because the downwelling flow in-  
435 cludes both the residual diabatic upwelling along the ridge as well as the net diabatic downwelling  
436 by the relaxation condition in the southern restoring region, which is concentrated on the eastern  
437 continental slope. Nonetheless, the zonal overturning streamfunction provides a qualitative sense  
438 of the zonal overturning circulations driven by mixing layer dynamics along the mid-ocean ridge.

439 The depth-integrated circulation in our simulations stands in contrast to that of Stommel and  
440 Arons (1959a)'s barotropic model and is the expression of a combination of various baroclinic  
441 deep western boundary currents and mixing layer flows (Figure 4a). Within 2000 km of the equa-  
442 tor, the northward and southward components of the deep western boundary currents alternatively  
443 dominate (compare with the meridional velocity at the equator in Figure 3). North of  $y = 2000$  km,  
444 the depth-integrated circulation is dominated by the along-slope flow in the bottom boundary layer,  
445 which is opposite the direction of Kelvin wave propagation. The depth-integrated circulation is  
446 strongly influenced by mixing layer dynamics, both near the boundaries and in the interior, and  
447 is structurally distinct from that predicted by the linear response to vortex stretching alone (Stom-  
448 mel and Arons 1959b; Pedlosky 1992; Cember 1998). Sverdrup balance only holds far from the

449 boundaries and accounts for little of the net transport compared to the abyssal mixing layer and  
450 western boundary current flows, where friction is important.

451 *c. Partially-Compensating Watermass Transformations*

452 The watermass transformation represents the net flow across a buoyancy surface driven by di-  
453 abatic forcing. Watermass transformation in the PGCM is driven by: bottom-enhanced turbulent  
454 mixing (positive in the net), restoring to a reference buoyancy profile in the southern restoring  
455 region (negative in the net). In the northern hemisphere, the restoring rate vanishes by construc-  
456 tion and watermass transformation is dominated by the mixing-driven component. Its calculation,  
457 following Walin (1982) and Ferrari et al. (2016), is given by

$$T(b) = \frac{\partial}{\partial b} \int_{V_{b' < b}} \nabla \cdot (\kappa \nabla b') dV, \quad (18)$$

458 where  $V_{b' < b}$  is the volume of water less buoyant than  $b$ . Watermass transformation is conveniently  
459 expressed in units of volumetric transport ( $\text{m}^3/\text{s}$ ) and can be decomposed into various contribu-  
460 tions. When applied to regions of bottom-enhanced mixing in the abyss, it is informative to de-  
461 compose the net watermass transformation into the typically negative contribution (balanced by  
462 diapycnal downwelling) in the SML and the typically positive contribution (balanced by diapycnal  
463 upwelling) in the BBL (e.g. Ferrari et al. 2016; McDougall and Ferrari 2017). For the purposes  
464 of watermass transformation calculations in this paper, we define the BBL as the layer with a  
465 convergent buoyancy flux,  $\nabla \cdot (\kappa \nabla b) > 0$ , which extends upwards from the seafloor to the level  
466 at which buoyancy flux attains its maximum magnitude; the remainder of the ocean is considered  
467 the SML and is dominated by a buoyancy flux divergence,  $\nabla \cdot (\kappa \nabla b) < 0$ . For convenience, all  
468 watermass transformations in this paper are computed in buoyancy space and remapped into depth

469 space according to the average depth of buoyancy surfaces,

$$\bar{z}(b) = \frac{1}{A(b)} \int z(b) dA, \quad (19)$$

470 which facilitates comparison across simulations with dramatically different stratifications and  
 471 against the fixed depths of topographic features in the ocean.

472 The net northern hemisphere watermass transformation of  $T_{\text{net}} = 1.6$  Sv at 3750 m (Figure 5a),  
 473 where it reaches its maximum, is consistent with the depth and magnitude of the maximum of  
 474 the MOC streamfunction at the equator (Figure 4b). The net watermass transformation  $T_{\text{net}} =$   
 475  $T_{\text{BBL}} + T_{\text{SML}} = 1.6$  Sv (black line) is the residual of a positive contribution of  $T_{\text{BBL}} = 2.1$  Sv from  
 476 the BBL (red line) and a negative contribution of  $T_{\text{SML}} = -0.5$  Sv from the SML (blue line), both  
 477 of which are dominated by the vertical component of the buoyancy flux divergence (dashed lines),  
 478 i.e.

$$T(b) = \partial_b \int_{V_{b' < b}} \nabla \cdot (\kappa \nabla b') dV \simeq \partial_b \int_{V_{b' < b}} \partial_z (\kappa \partial_z b') dV. \quad (20)$$

479 Virtually all of this transformation occurs on the flanks of the mid-ocean ridge (Figure 5b).

480 For the convenience of being able to ignore meridional variations in the basin geometry (and  
 481 their effects on watermass transformations via the “perimeter” effect, as described by Holmes  
 482 et al. 2018), we limit the remaining discussion to a domain from  $L/2 < x < 3L/2$  and  $0 < y < L/2$   
 483 along the north-hemisphere mid-ocean ridge, which is responsible for roughly 1 Sv of the full  
 484 basin’s transformation (Figure 5c; limited domain outlined in Figure 2a).

485 The net watermass transformation  $T_{\text{net}} = 1$  Sv at equilibrium is much larger than the  $L\Psi_{\text{bg}} \leq$   
 486  $0.1$  Sv predicted by the integral constraint (eq. 5) from 1D boundary layer theory. To clarify  
 487 the discrepancy between the watermass transformations that emerge from the 3D PGCM and the  
 488 watermass transformations predicted by 1D dynamics, we emulate the 3D PGCM simulation by  
 489 solving the 1D boundary layer equations locally and interpolating onto the 3D PGCM grid.

## 490 5. Emulating the 3D PGCM with local 1D boundary layer models

### 491 a. Boundary layer theory

492 Following CF18, we transform the planetary-geostrophic equations (6) - (8) from the Cartesian  
 493 coordinates  $(x, y, z)$  to a coordinate system  $(x', y', z')$  aligned with an infinitely extending sea floor at  
 494  $z = x \tan \theta$ , with slope angle  $\theta$ , and ignoring the southern region restoring condition on buoyancy.  
 495 The transformation is given by  $x' = x \cos \theta + z \sin \theta$ ,  $y' = y$ ,  $z' = -x \sin \theta + z \cos \theta$ . Buoyancy  
 496  $b = B(z) + b'$  is decomposed into a background  $B(z)$  with constant stratification  $\partial_z B = N_0^2$  and an  
 497 anomaly  $b'(z')$ . The steady state boundary layer equations are thus given by:

$$-f \cos \theta u^{y'} = b' \sin \theta - r \cos \theta^2 u^{x'} \quad (21)$$

$$f \cos \theta u^{x'} = -r u^{y'} \quad (22)$$

$$u^{x'} N_0^2 \sin \theta = \partial_{z'} [\kappa (N^2 \cos \theta + \partial_{z'} b')] , \quad (23)$$

498 with a no-flux boundary condition  $\partial_{z'} b' + N_0^2 \cos \theta = 0$  at the seafloor  $z' = 0$  and decay conditions  
 499  $\partial_{z'} u^{x'}, \partial_{z'} u^{y'}, \partial_{z'} b' \rightarrow 0$  as  $z' \rightarrow 0$ . These equations yield exact analytical solutions for constant  $\kappa$   
 500 (Callies 2018) and approximate analytical solutions for elementary structures  $\kappa(z)$  profiles (Callies  
 501 2018).

### 502 b. Emulator setup

503 We emulate the PGCM solution by using finite differences to solve the time-dependent  
 504 boundary-layer equations (21) - (23) with the local Coriolis parameter  $f(y)$  and slope angle  $\theta(x, y)$   
 505 at each  $(x, y) = (\xi, \eta)$  of the PGCM grid, which is a sensible approach given that the parameters  
 506  $f(y)$  and  $\theta(x, y)$  vary on scales larger than the those of the boundary-layer solutions (Dell and Pratt  
 507 2015). Since these local boundary layer solutions are given in terms of the local slope-normal di-  
 508 rection  $z'$  rather than the true vertical direction  $z$ , we project the solution onto the true vertical

509 direction  $z$  with the substitution  $z' \rightarrow z/\cos\theta$  and linearly interpolate from the projected  $z$ -levels  
510 of the boundary layer solution to the PGCM's local  $\sigma$ -levels. This process provides an emulator  
511 of the PGCM which is purely the result of local 1D dynamics but is re-gridded to the same grid as  
512 the 3D PGCM and can thus be directly compared.

### 513 *c. Emulator evaluation*

514 We evaluate the emulator against the spin-up of a PGCM simulation with a constant stratification  
515 initial condition  $N_0^2$ , hereafter PGCM-CONST. The 1D emulator accurately reproduces the initial  
516 spin-up of buoyancy and velocity fields of the PGCM-CONST simulation along most of the mid-  
517 ocean ridge flanks, but fails at the top and bottom of the ridge where the topographic curvature is  
518 large and the cross-slope convergences omitted by 1D dynamics become important (Figure 6a,b).

519 As the solution nears equilibrium, however, the interior basin stratification drifts away from its  
520 constant initial value (compare gray and black contours in Figure 6d) and the boundary layer flows  
521 diverge from the 1D emulator's prediction (Figure 6c,d). This is expected, as the basin stratification  
522 of PGCM-CONST is allowed to evolve in response to the 3D circulation while the background  
523 interior stratification  $N_0^2$  is a constant parameter in the emulator. Relative to the emulator, the  
524 equilibrium PGCM-CONST solution exhibits reduced downwelling in the SML and enhanced  
525 upwelling in the BBL, both of which contribute to enhancing the net diapycnal upwelling. In  
526 Section 6, we use the 1D emulator to identify properties of the watermass transformations in the  
527 PGCM that can be explained by one-dimensional dynamics alone.

## 528 **6. The Effect of Variable Interior Stratification on the Abyssal Circulation**

### 529 *a. What sets the abyssal stratification?*

530 In our PGCM simulations, the drift of interior buoyancy surfaces over time (Figure 6d) suggests  
531 that the interior stratification at equilibrium may differ substantially from the stratification of the  
532 southern region buoyancy profile. Figure 7a shows the temporal evolution of the horizontally-  
533 averaged vertical stratification profile, averaged over the northern hemisphere basin in the PGCM,  
534 where darker greys represent later times. In PGCM-CONST, the abyssal stratification develops  
535 substantial vertical structure in the basin over time, despite being rapidly restored back to a con-  
536 stant stratification in the southern restoring region (solid lines, Figure 7a). Net watermass trans-  
537 formation is initially unbalanced by diapycnal flow (compare Figure 8b,c) and thus drives changes  
538 in the volume of buoyancy layers. Excess watermass transformations near the base of the slope  
539 destroys the densest layers and expands the deep layers, which translates into a reduction of the  
540 stratification that originates at the bottom of the ridge and propagates upwards over time. The  
541 details of the vertical structure of the equilibrium basin stratification depend on ridge height (not  
542 shown), but in all cases the basin stratification increases from zero at the maximum depth (im-  
543 posed by the no-flux condition at the flat bottom) up to near the restoring reference value at the  
544 top boundary.

545 The zonal-mean basin stratification develops a significant meridional structure, wherein the  
546 zonal-mean stratification along the ridge weakens with distance from the Southern restoring re-  
547 gion (Figure 7b,c). In contrast to the mixing layer stratification, which is strongest at the equa-  
548 tor and weaker polewards (Callies 2018, CF18), the zonal-mean stratification decreases roughly  
549 monotonically with increasing latitude.

550 Simulations using a reference buoyancy profile that corresponds to an exponential stratification  
 551 with decay scale of  $\delta = 1000$  m exhibit much less drift in their stratifications over time (dashed  
 552 lines, Figure 7a,b). Although the equilibrium basin stratifications in all of the different PGCM  
 553 experiments develop vertical structure, there does not seem to be a single preferred equilibrium  
 554 stratification that depends only on the mixing: both the geometry of the abyssal topography and the  
 555 restoring profile in the southern restoring region influence the interior stratification at equilibrium.

556 *b. Effect of variable stratification on watermass transformations*

557 We begin by considering the case of transient spin-up from a reference buoyancy profile with  
 558 constant stratification  $N_0^2$ , PGCM-CONST. It is useful to consider the evolution of the PGCM  
 559 during its initial spin-up ( $\hat{t} \simeq \tau_{\text{BL}}/\tau = 0.1$ ) when only mixing layer dynamics are relevant and  
 560 the solution is thus well-predicted by the 1D Emulator (Figure 6). Figure 8a shows the water-  
 561 mass transformations in the 1D Emulator at  $\hat{t} = 0.1$ , which almost exactly predicts the watermass  
 562 transformations in the full 3D PGCM (Figure 8b).

563 Between  $-4200 \text{ m} < z < -3000 \text{ m}$ , where the slope of the mid-ocean ridge is roughly constant,  
 564 the near-boundary flow exhibits a vanishingly small net transport (solid black line in Figure 8a),  
 565 which is approximately equal to the integral constraint  $T_{\text{net}} \simeq L\Psi_{\text{bg}} = L\kappa_{\text{bg}} \cot \theta \leq 0.1$  Sv predicted  
 566 by 1D boundary layer theory (dashed black line in Figure 8a). This vanishingly small net transport  
 567 is the result of large positive transformation  $T_{\text{BBL}}$  (diabatic upwelling, in red) in the BBL and  
 568 almost-as-large negative transformation  $T_{\text{SML}}$  (diabatic downwelling, in blue) in the SML. Below  
 569  $z = -4200$  m, at the base of the topographic slope, abyssal bottom waters feed the upwelling in the  
 570 BBL and the maximum net watermass transformation is well predicted by the strictly upwelling  
 571 transport in the bottom boundary layer from 1D theory (Figure 8a,b), as suggested by CF18.

572 For the spin-up from a reference stratification that increases exponentially with height (as is  
 573 almost ubiquitously the case in the abyssal ocean), the integral constraint (eq. 5) no longer holds  
 574 at  $\hat{t} = 0.1$  and the solution already exhibits a net transformation much larger than  $L\Psi_{bg}$  at all depths  
 575 from the base of the slope to the ridge crest (Figure 8c,d). The increase in the net transformation,  
 576 which spans the full vertical extent of the ridge, is primarily due to a decrease in the downwelling  
 577 in the SML which, in the extreme case of an exponential scale height of  $\delta = 500$  m for the restoring  
 578 stratification, vanishes completely (Figure 8d). The strongly positive net transformation is largely  
 579 due to the buoyancy convergence driven by the rapid increase of the initial stratification with  
 580 height, i.e.  $\kappa\partial_{zz}B > 0$  reduces the divergence  $\nabla \cdot (\kappa\nabla b) < 0$  in the SML (see also Figure 14).

581 As these solutions reach equilibrium, they retain a finite net transformation at all depths from  
 582 the base of the slope to the ridge crest, slightly reduced by gradually strengthening negative trans-  
 583 formations in the SML (compare Figure 8g,h to Figure 8c,d). At equilibrium, we find the degree  
 584 of compensation near the ridge crest depends on the vertical scale over which the restoring stratifi-  
 585 cation varies (within a range applicable to the ocean): the more rapidly the stratification increases  
 586 with height, the less upwelling in the BBL is compensated by downwelling in the SML (Figure  
 587 8f-h and Figure 9). In contrast, upwelling in the BBL is remarkably invariant to vertical variations  
 588 in the stratification and remains a reasonable prediction for the maximum net transformation (Fig-  
 589 ure 9a,b), which occurs at the base of the slope where the compensating downwelling contribution  
 590 from the SML vanishes (Figure 9c). Thus, while the maximum net watermass transformation is  
 591 accurately predicted by upwelling in the BBL alone, the vertical structure and extent of watermass  
 592 transformations depend also on downwelling in the SML, which itself is strongly dependent on  
 593 the vertical stratification, and is not predicted by 1D theory.

594 *c. Vertical extent of overturning set by ridge height*

595 We have shown that most of the watermass transformation occurs within abyssal mixing layers  
596 along the mid-ocean ridge (Figure 5a,b). We further hypothesize that variations in the height of  
597 the ridge modulate the vertical extent of abyssal watermass transformations and thus the vertical  
598 extent of the abyssal overturning cell. We test this hypothesis by running variations of the PGCM-  
599 CONST where we vary the ridge height from 500 m to 2000 m, in increments of 500 m. In the  
600 initial spin-up, largely compensating positive and negative transformations develop in the BBL  
601 and SML, respectively, from the base of the ridge slope up to the ridge crest (Figure 10a-d). The  
602 net transformation below the ridge crest vanishes according to the integral constraint (eq. 5),  
603 except near the sea-floor where bottom water feeds into the BBL. At equilibrium, however, the  
604 stratification drifts away from its constant reference state (e.g. Figure 7) and permits a finite net  
605 transformation (Figure 10e-h), which spans the full vertical extent of the ridge. The result that the  
606 vertical extent of the abyssal MOC follows the vertical extent of the mid-ocean ridge is consistent  
607 with Lumpkin and Speer (2007)'s global inversion for the MOC, which shows that the vertical  
608 extent of the Atlantic and Indo-Pacific lower MOC cells appear to closely follow the vertical  
609 extent of their respective major bathymetric features (i.e. mid-ocean ridges).

610 **7. Comparison with realistic mid-ocean ridges**

611 The topography and mixing in the PGCM is inspired by observations from the Brazil Basin (Fig-  
612 ure 11), one of the regions of the abyssal ocean best characterized by observations (e.g. St. Laurent  
613 et al. 2001; Thurnherr and Speer 2003). The circulation that emerges from the PGCM-REAL sim-  
614 ulation (Figure 11b) is qualitatively similar to the circulation inferred from observations using an  
615 inverse model (Figure 11a, based on St. Laurent et al. 2001): bottom-enhanced mixing along the

616 slope of the mid-ocean ridge drives upwelling in a bottom boundary layer and downwelling in a  
617 stratified mixing layer above.

618 To contextualize our simulated watermass transformations, we estimate watermass transforma-  
619 tions in the ocean based on hydrography and a commonly-used mixing parameterization, follow-  
620 ing Ferrari et al. (2016)’s modifications of Nikurashin and Ferrari (2013). The buoyancy flux is  
621 parameterized by  $\overline{w'b'} = -\Gamma\varepsilon$ , where  $\varepsilon$  is the kinetic energy dissipation and  $\Gamma$  is a ‘mixing effi-  
622 ciency’ set to  $\Gamma = 0.2$  (Osborn 1980); the buoyancy field (computed from the neutral density  $\gamma$ ) is  
623 taken from a gridded product derived from hydrographic sections of the World Ocean Circulation  
624 Experiment (Gouretski and Koltermann 2004); and we impose the insulating bottom boundary  
625 condition  $\mathbf{n} \cdot \overline{\mathbf{u}'b'} \simeq \overline{w'b'} = 0$  (where  $\mathbf{n} \simeq \mathbf{z}$  for typical bathymetric slopes of  $\tan \theta \ll 1$ ). The dis-  
626 sipation rate  $\varepsilon$  is produced by applying linear wave radiation theory for internal tides (Nycander  
627 2005) and lee waves (Nikurashin and Ferrari 2011) and assuming a fraction  $q = 0.3$  of the radiated  
628 energy is locally dissipated according to a bottom-enhanced structure function with a height scale  
629 of 500 m (St. Laurent and Garrett 2002). We compare watermass transformation estimates from  
630 the ocean with estimates from PGCM-REAL, a simulation with restoring to an exponential refer-  
631 ence stratification with a decay scale of 1000 m and which is our simulation with a stratification  
632 in the southern restoring region most similar to the Southern Ocean’s (Figure 2c). We focus on  
633 rectangular regions with dimensions 3000 km by 3000 km (in the PGCM) or  $30^\circ$  longitude by  $30^\circ$   
634 latitude (in the ocean), which encompass comparable ridge lengths and surface areas at subtropical  
635 latitudes. Watermass transformations in the PGCM-REAL simulation (Figure 12a) are the result  
636 of partially compensating buoyancy flux convergence (Figure 12e) in the BBL (red colors) and  
637 buoyancy flux divergence in the SML (blue colors). Qualitatively similar (but noisier) watermass  
638 transformations emerge for the mid-ocean ridge regions in the Pacific, Atlantic, and Indian (Figure  
639 12b-d, regions delineated by boxes in panels e,f). While the net transformation varies from 0.5

640 Sv in the South Pacific region to 2 Sv in the Indian Ocean region, the net transformation is al-  
641 ways the result of partially compensating upwelling and downwelling. This qualitative similarity  
642 emerges in the large-scale watermass diagnostic, despite the relatively heterogeneous nature of the  
643 estimated buoyancy flux and topography in the ocean basins (compare Figure 12f, e), because in  
644 all cases the turbulent buoyancy flux is bottom-enhanced (driving downwelling) and tapers to zero  
645 over the last grid cell to meet the insulating boundary condition within some bottom boundary  
646 layer (driving upwelling). This property of compensating watermass transformations is in contrast  
647 to the case of a constant buoyancy flux (Ferrari et al. 2016; Holmes et al. 2018), in which there is  
648 no compensating downwelling. Estimates of *global* abyssal watermass transformations, however,  
649 exhibit stronger compensation by downwelling in the SML than shown here for mid-ocean ridge  
650 regions (by factors of 2 and 3 for Ferrari et al. 2016 and McDougall and Ferrari 2017, respectively).  
651 In Section 8 we present evidence in support of McDougall and Ferrari (2017)'s speculation that  
652 much of this discrepancy arises due to the effects of correlations between the buoyancy flux and  
653 the stratification, which are omitted in their calculations. Ferrari et al. (2016)'s estimate includes  
654 these correlation terms but relies on poorly-sampled knowledge of the buoyancy flux and stratifi-  
655 cation close to the seafloor, which likely introduces substantial uncertainty in their estimate. While  
656 much work has gone into understanding how the compensation factor depends on various param-  
657 eters of the diagnostic approach (McDougall and Ferrari 2017; Holmes et al. 2018; Cimoli et al.  
658 2019), the functional dependence of the compensation factor in the prognostic dynamic approach  
659 has received comparably little attention and is not well known.

## 660 **8. Classic recipes and new trends in abyssal cuisine**

661 Quantitative study of the abyssal stratification began with the classic study of Munk (1966): a  
662 point-wise theory in which the observed abyssal stratification is the result of a balance between

663 uniform upwelling and a uniform turbulent vertical mixing. As anticipated by Munk (1966), sub-  
664 sequent observations show turbulent mixing to be strongly heterogeneous, with an emerging pat-  
665 tern of weak background mixing and vigorous mixing near rough topography (Polzin et al. 1997;  
666 Waterhouse et al. 2014). In light of these observations, Munk and Wunsch (1998) revisited Munk  
667 (1966)’s theorized point-wise vertical balance and re-derive it as a horizontally-averaged buoyancy  
668 budget, which we transcribe as

$$\langle w \rangle A \simeq \langle N^2 \rangle^{-1} \frac{d}{dz} [A(z) \langle \kappa \rangle \langle N^2 \rangle] \quad (24)$$

669 in our notation, where the key assumption is that correlations between the turbulent diffusivity  
670  $\kappa$ , the stratification  $N^2$ , and the vertical velocity  $w$  are all assumed to be negligible, such that  
671  $\langle wN^2 \rangle = \langle w \rangle \langle N^2 \rangle$  and  $\langle \kappa N^2 \rangle = \langle \kappa \rangle \langle N^2 \rangle$ . In Figure 13a,b,c, we show, respectively, the three terms  
672 in eq. 24: the horizontally-averaged stratification  $\langle N^2 \rangle$ , the turbulent buoyancy flux  $\langle \kappa \rangle \langle N^2 \rangle$ ,  
673 and the isobath surface area (ocean area at a fixed depth)  $A(z)$ . In Figure 13d we show the left-  
674 and right-hand sides of eq. 24 in the PGCM-REAL simulation at equilibrium. The horizontally-  
675 averaged vertical flux divergence (right-hand side of eq. 24) is a poor prediction for the diagnosed  
676 vertical transport. This is not surprising, given that 1)  $w$ ,  $N^2$ , and  $\kappa$  are spatially-correlated in our  
677 solutions and 2) that density surfaces are strongly sloping near boundaries. Analysis in buoyancy  
678 coordinates, such as either the thickness-weighted average framework (De Szoeke and Bennett  
679 1993; Young 2011) or the watermass transformation framework (Walín 1982), are more appropri-  
680 ate. At equilibrium, the mixing-driven watermass transformation (solid black line) exactly equals  
681 the diapycnal transport (the diabatic MOC of interest here) but also serves as a better approxima-  
682 tion of the vertical transport  $\langle w \rangle A$  than the right hand side of eq. 24.

683 In Figure 13c, we show that ignoring correlations within the buoyancy flux  $\langle \kappa N^2 \rangle \approx \langle \kappa \rangle \langle N^2 \rangle$   
684 introduces large biases relative to the full horizontal-mean buoyancy flux, which results in even

685 larger biases in the flux divergence (Figure 13d). To investigate the role of these spatial correlations  
686 between  $\kappa$  and  $N^2$  more exactly, we return to the watermass transformation framework, where we  
687 now define  $\langle \cdot \rangle \equiv A_b^{-1} \int_{A_b} \cdot dA$  as the average along a buoyancy surface. We can thus decompose the  
688 vertical component of the watermass transformation into uncorrelated and correlated components,  
689 respectively:

$$T_{\text{net}} \approx \partial_b (A \langle \kappa \partial_z b \rangle) = \partial_b (A \langle \kappa \rangle \langle \partial_z b \rangle) + \partial_b (A \langle \kappa' \partial_z b' \rangle), \quad (25)$$

690 where  $\kappa' = \kappa - \langle \kappa \rangle$  and  $\partial_z b' = \partial_z b - \langle \partial_z b \rangle$  are deviations from the mean along a buoyancy surface.  
691 Figures 14a,c show that ignoring the correlation terms in the watermass transformation results in  
692 an overestimation of the net transformation by 20 to 200% because the stratification  $\partial_z b'$  is locally  
693 reduced in the abyssal mixing layers where  $\kappa'$  is high, with the magnitude of this bias varying  
694 dramatically across simulations with different topographic geometries and restoring profiles.

695 To support our hypothesis that vertical variations in the stratification are necessary to support  
696 large net watermass transformations, we further decompose the uncorrelated component into a  
697 component related to the change in the mean stratification and a residual component related to  
698 changes in both the area of the buoyancy surface and the mean diffusivity, respectively:

$$\partial_b (A \langle \kappa \rangle \langle \partial_z b \rangle) = A \langle \kappa \rangle \partial_b \langle \partial_z b \rangle + (\partial_z b) \partial_b (A \langle \kappa \rangle). \quad (26)$$

699 In the experiment shown in Figure 14b, where the uncorrelated component is a reasonable approx-  
700 imation of the net transformation, we find the net transformation to be largely driven by variations  
701 of the stratification with buoyancy,  $A \langle \kappa \rangle \partial_b \langle \partial_z b \rangle$ . Variations in the stratification also appear im-  
702 portant in the experiment shown in Figure 14d, although this decomposition is more difficult to  
703 interpret since the uncorrelated component overestimates the net transformation by a factor of 3  
704 (Figure 14c).

## 705 **9. Discussion**

706 The idealized numerical model presented here describes an abyssal circulation and stratification  
707 controlled by mixing-driven flows along a mid-ocean ridge in a cross-equatorial basin (Figure 1).  
708 By initializing with- and restoring to- a series of reference buoyancy profiles in the south of the  
709 basin, we investigate transient and equilibrium coupling between the basin stratification and the  
710 mixing-driven boundary flows. At equilibrium, dense abyssal waters form in the southern restoring  
711 region and flow north via adiabatic deep western boundary currents (red circle), filling the abyssal  
712 depths in both hemispheres. Along the mid-ocean ridge, bottom-enhanced mixing (squiggly lines)  
713 drives a net transformation of dense abyssal waters into lighter deep waters (dashed arrows), the  
714 residual of partially-compensating upwelling in a bottom boundary layer (BBL) and downwelling  
715 in a stratified mixing layer (SML) right above it. The newly formed light deep waters flow zonally  
716 towards the western continental slope (solid arrow), returning southward via an adiabatic deep  
717 western boundary current to the restoring region (blue circles), and closing the abyssal overturning  
718 circulation as they are once again transformed into dense abyssal waters.

719 Despite the extreme degree of idealization in our formulation of the Planetary Geostrophic Cir-  
720 culation Model (PGCM), the watermass transformations that emerge at equilibrium are qualita-  
721 tively similar to diagnostic estimates of watermass transformations near mid-ocean ridges in the  
722 Pacific, Atlantic, and Indian Oceans (Figure 12), which are themselves fairly uncertain (Cimoli  
723 et al. 2019). Similarly, the zonal overturning that emerges within bottom mixing-driven flows  
724 along the mid-ocean ridge are qualitatively similar to that described by an inverse model of the  
725 abyssal Brazil Basin based on in-situ measurements (St. Laurent et al. 2001, and Fig. 11). Re-  
726 maining differences between our simulations and observations are likely due to the crude nature

727 of our parameterizations for the restratification by submesoscale turbulence and for the formation  
728 of bottom waters in the Southern Ocean, as well as uncertainties in the observational estimates.

729 The equilibrium interior stratification in the PGCM always exhibits dynamically significant ver-  
730 tical variations, the structure of which is determined by a combination of mixing layer dynamics  
731 and the restoring condition in the south. Even in our simulations that are initialized from- and  
732 restored to- a constant stratification reference buoyancy profile, heterogeneities in the topographic  
733 slope cause cross-slope divergence and a corresponding exchange flow between the abyssal mix-  
734 ing layers and the interior. Over time, these exchange flows modify the interior stratification and  
735 associated watermass transformations.

736 As in CF18, we find the prediction of upwelling in the BBL by one-dimensional (1D) boundary  
737 layer theory provides a reasonable approximation to the maximum net transformation or, equiv-  
738 alently, the strength of the diabatic meridional overturning circulation (Figures 8 and 9). While  
739 this interpretation provides a useful prediction for the maximum net transformation which occurs  
740 at the base of topographic slopes, it does not inform the net transformation along the flanks of the  
741 mid-ocean ridge, where upwelling in the BBL is instead partially compensated by downwelling in  
742 a SML. At depths where both the BBL and the SML are active, 1D theory predicts almost perfect  
743 compensation and a resulting net transformation that is vanishingly small (eq. 5 and Figure 8a,e).  
744 In contrast, our PGCM simulations exhibit finite net watermass transformations that extend from  
745 the base of the ridge slopes all the way up to the ridge crest (Figure 10), consistent with both  
746 our oceanic estimates (Figure 12) and inverse models of the Indo-Pacific overturning circulation  
747 (Lumpkin and Speer 2007). We attribute the existence of a finite net transformation to vertical  
748 variations in the basin stratification (Figures 8 and 14). As we increase the degree to which the  
749 restoring stratification varies in the vertical, the compensation of BBL upwelling by SML down-  
750 welling (evaluated near the depth of the ridge crest) ranges from nearly-perfect compensation to

751 nearly-zero compensation (Figure 9a). Thus, while 1D bottom boundary layer theory provides a  
752 reasonable approximation to *maximum net* watermass transformation, the vertical extent and struc-  
753 ture of watermass transformations depends on the degree of compensation by downwelling in the  
754 SML, which is itself coupled to the vertically-varying basin stratification.

755 Our simulations show that correlations between mixing and stratification (Figure 14a,c), which  
756 are typically ignored in idealized models of the zonal-mean abyssal overturning (Nikurashin and  
757 Vallis 2011; Jansen and Nadeau 2019), can be of leading-order importance in abyssal watermass  
758 transformations; whether these correlations are important in the ocean remains an open question.  
759 Despite our improved understanding of the roles of bottom mixing and the interior basin strat-  
760 ification on the abyssal watermass transformations and circulation, we fall short of a predictive  
761 analytical theory for the abyssal overturning and stratification that couples boundary layer dynam-  
762 ics with a model for the evolution of the interior stratification. Recent and ongoing work in 1)  
763 observing abyssal mixing layers (e.g. Garabato et al. 2019), 2) investigating their dynamics with  
764 idealized theory and simulations (Wenegrat et al. 2018; Callies 2018; Holmes et al. 2019), 3) de-  
765 veloping and evaluating parameterizations of their turbulent fluxes, 4) and coupling them to the  
766 basin stratification (e.g. refining the approach of Salmun et al. 1991) will all be key ingredients  
767 for cooking up a revised theory of the abyssal circulation and stratification.

768 *Acknowledgments.* We thank Ali Mashayek, Laura Cimoli, Xiaozhou Ruan, Bryan Kaiser, and  
769 Ryan Holmes for insightful discussions about abyssal mixing layers. We thank two reviewers for  
770 feedback that improved the manuscript. We acknowledge funding support from National Science  
771 Foundation awards 6932401 and 6936732.

## LIST OF FIGURES

1058		
1059	<b>Fig. 1.</b>	Schematic of a basin-scale abyssal circulation driven by near-boundary mixing. Dense bot-
1060		tom waters flow northward out of the Southern Ocean via a deep western boundary current
1061		(red circle) along the smooth and relatively quiescent continental slope, where little water-
1062		mass transformation occurs. A cross-basin zonal flow feeds bottom waters from the deep
1063		western boundary current into a system of abyssal mixing layers driven by bottom-enhanced
1064		turbulent mixing over the rough topography of the mid-ocean ridge flanks (squiggly or-
1065		ange arrows). The turbulent buoyancy flux converges in a bottom boundary layer (BBL),
1066		driving vigorous diabatic upwelling across buoyancy surfaces (grey lines). In a stratified
1067		mixing layer (SML) above, the buoyancy flux diverges, driving diabatic downwelling. The
1068		net effect of the up- and down-welling in the abyssal mixing layers is a net transformation
1069		(dashed arrows) of bottom waters into deep waters. The newly formed deep waters return
1070		via cross-basin zonal flows to the smooth continental slope, wherein they flow southward
1071		in a deep western boundary current (blue circles) to close the abyssal circulation in the South-
1072		ern Ocean. For simplicity, we omit the alternating along-flank flows (see Figure 3b) that are
1073		in frictional thermal-wind balance with the plunging isopycnals. . . . . 56
1074	<b>Fig. 2.</b>	Configuration of the Planetary Geostrophic Circulation Model (PGCM). (a) Seafloor depth
1075		in the PGCM. We highlight the southern restoring region where we apply a buoyancy restor-
1076		ing which acts to transform deep waters into bottom waters (see Section 3c) and a northern-
1077		hemisphere region in which we diagnose watermass transformations along the mid-ocean
1078		ridge (see Section 4c). (b) Zonal section of the imposed turbulent diffusivity $\kappa$ , which is
1079		bottom-enhanced over the mid-ocean ridge. (c) The red lines show the four stratification
1080		profiles $B_z$ used in the PGCM as both the initial condition and as the reference profile for
1081		buoyancy restoring in the southern restoring region. The black line shows the observed strat-
1082		ification profile from the World Ocean Circulation Experiment (Gouretski and Koltermann
1083		2004) in the South Pacific, averaged horizontally from 55°S to 45°S and 175°E to 115°W. . . . . 57
1084	<b>Fig. 3.</b>	Cartesian components of the velocity vector in the PGCM-REAL simulation along: (a-c)
1085		a mid-latitude section in the northern hemisphere, $y = 3000$ km, and (d-f) a section at the
1086		equator, $y = 0$ km. Black lines show three equally spaced buoyancy surfaces. . . . . 58
1087	<b>Fig. 4.</b>	(a) Barotropic, (b) meridional, and (c) zonal overturning circulations in the PGCM-REAL
1088		simulation (see definitions in Section 4b). In all cases, positive values (red) correspond to
1089		counter-clockwise circulations. The red and blue solid lines in (b) and (c), respectively,
1090		show the height of the mid-ocean ridge along the dashed lines of the same colors in (a).
1091		The thick black lines in (a) are the 3000 m and 4000 m isobaths, which highlight both the
1092		continental slopes and the mid-ocean ridge. The thin black lines in (b) and (c) are equally-
1093		spaced buoyancy surfaces, sampled at $x = L/4$ and $y = L/2$ , respectively. . . . . 59
1094	<b>Fig. 5.</b>	Watermass transformations from the PGCM-REAL simulation in (a) the full northern hemi-
1095		sphere basin ( $y > 0$ ), (b) along the northern-hemisphere mid-ocean ridge ( $y > 0$ , $L/2 < x <$
1096		$3L/2$ ), and (c) in a limited watermass analysis region along the northern-hemisphere mid-
1097		-ocean ridge ( $0 < y < L/2$ , $L/2 < x < 3L/2$ ) highlighted in Figure 2. The black line shows
1098		the net watermass transformation, defined by equation (18). The red and blue lines show the
1099		contributions from the bottom boundary layer (BBL) and the stratified mixing layer above
1100		(SML). The dashed lines show the contributions from only the vertical component of the
1101		buoyancy flux. All watermass transformations in the paper are computed in buoyancy space
1102		and remapped into depth space (according to eq. 19). . . . . 60
1103	<b>Fig. 6.</b>	Vertical velocity (colors) and buoyancy surfaces (black lines) in abyssal mixing layers along
1104		a zonal section at $y = L/2$ that crosses the mid-ocean ridge in (a,c) the 1D PGCM emulator

1105 and (b,d) the full 3D PGCM, where both are initialized from identical constant stratification  
 1106 buoyancy fields. The top row shows the solutions at an initial time  $\hat{t} = 0.1$ , at which point the  
 1107 abyssal mixing layers have spun up but the basin-scale circulation has not (see Section 3d).  
 1108 The bottom row shows the solution at  $\hat{t} = 50$ , at which point the full solution has roughly  
 1109 come to equilibrium with the buoyancy restoring in the Southern Ocean. The predicted  
 1110 buoyancy surfaces in (a,c) are reproduced as dashed grey lines in (b,d) to show how the 1D  
 1111 emulator predicts the buoyancy field well for short times but that the interior stratification in  
 1112 the PGCM drifts far from the 1D emulator’s prediction as it approaches equilibrium. . . . . 61

1113 **Fig. 7.** (a) Temporal evolution and (b,c) meridional structure of the stratification in PGCM simu-  
 1114 lations. Grey-scale lines in (a) show the temporal evolution of the horizontal-mean strati-  
 1115 fication in the Northern Hemisphere for simulations with a constant stratification restoring  
 1116 buoyancy profile (solid lines) and a restoring buoyancy profile corresponding to stratification  
 1117 that decays with depth with a scale height of  $\delta = 1000$  m (dashed lines). The dashed brown  
 1118 line delineates the height of the ridge crest. Panels (b) and (c) show the zonal-mean strati-  
 1119 fication at equilibrium  $\hat{t} = 50$  (colors) and equally-spaced buoyancy surfaces (black lines) for  
 1120 experiments with restoring to constant and exponential stratification, respectively. . . . . 62

1121 **Fig. 8.** Watermass transformations in: (a, e) a 1D emulator of the PGCM and (b-d, f-h) the 3D  
 1122 PGCM simulations with restoring buoyancy profiles corresponding to stratification profiles  
 1123 with various exponential scale heights  $\delta$  (we recover  $N^2 = \text{constant}$  as  $\delta \rightarrow \infty$ ). The initial  
 1124 spin-up at  $\hat{t} = 0.1$  is shown in (a-d) and the equilibrium state at  $\hat{t} = 50$  is show in (e-h).  
 1125 Black, red, and blue lines show the net, bottom boundary layer (BBL), and stratified mixing  
 1126 layer (SML) contributions to the watermass transformations, respectively. The black dashed  
 1127 line in (a,e) shows the integral constraint  $L\Psi_\infty = L\kappa_{\text{bg}} \cot \theta_{\text{max}}$  derived from boundary layer  
 1128 theory, where we take  $\theta_{\text{max}}$  as the maximum slope angle of the mid-ocean ridge flank. . . . . 63

1129 **Fig. 9.** Scaling of watermass transformations in mixing layers with (a) the height  $\delta$  over which the  
 1130 restoring stratification varies and (b) the bottom diffusivity  $\kappa_{\text{bot}}$ . Colored symbols represent  
 1131 the absolute value of the maximum transport in the BBL (red), the SML (blue), and the  
 1132 net (black), with squares and diamonds representing the PGCM-CONST and PGCM-REAL  
 1133 simulations, respectively. The grey shading in (a) represents realistic vertical scales  $\delta$  over  
 1134 which abyssal stratification varies and in (b) represents plausible values of the bottom dif-  
 1135 fusivity  $\kappa_{\text{bot}}$ . Panel (c) provides an example of the watermass transformations for a bottom  
 1136 diffusivity  $\kappa_{\text{bot}} = 5 \times 10^{-3} \text{ m}^2\text{s}^{-1}$ , a stratification height scale  $\delta = 1000$  m, and a ridge  
 1137 height of  $r_h = 1500$  m, where the corresponding maxima are marked by diamonds and the  
 1138 dashed brown line represents the ridge crest. In all experiments, the maximum net and BBL  
 1139 transformations occur at depths of roughly 4250 m, at the base of the ridge slope, while the  
 1140 maximum SML transformation occurs at the ridge crest. . . . . 64

1141 **Fig. 10.** Watermass transformations in PGCM simulations as a function of ridge height. All panels  
 1142 are for a fixed constant stratification restoring buoyancy profile. The initial spin-up at  $\hat{t} = 0.1$   
 1143 is shown in (a-d) and the equilibrium state at  $\hat{t} = 50$  is shown in (e-h). Mid-ocean ridge height  
 1144 increases in increments of 500 m from left to right, as indicated by the dashed brown lines.  
 1145 Black, red, and blue lines show the net, bottom boundary layer (BBL), and stratified mixing  
 1146 layer (SML) contributions to the watermass transformations, respectively. . . . . 65

1147 **Fig. 11.** Diabatic zonal overturning circulation driven by bottom-enhanced mixing on the western  
 1148 flank of a mid-ocean ridge in (a) the South Atlantic Ocean and (b) the PGCM-REAL simu-  
 1149 lation. White lines show arbitrarily chosen contours of the counter-clockwise zonal over-  
 1150 turning streamfunction, where the values for (a) are digitized from Figure 14 of St. Laurent  
 1151 et al. (2001) and for (b) are diagnosed from PGCM-REAL simulation. Coloring shows the  
 1152 vertical diffusivity in log-scale (light-grey shading represents depths with no microstructure

1153 measurements and does not necessarily represent topography), where panel (a) is inspired  
 1154 by Figure 2 of Polzin et al. (1997) and the diffusivity is calculated with microstructure pro-  
 1155 files from the BBTRE experiment (Polzin et al. 1997; St. Laurent et al. 2001, archived at  
 1156 microstructure.ucsd.edu). Black lines are: (a) potential density  $\sigma_4$  surfaces (referenced to  
 1157 4000 m) from the microstructure profiles and (b) buoyancy surfaces from the PGCM so-  
 1158 lution, chosen arbitrarily to show that the zonal overturning circulation is indeed diabatic.  
 1159 The dark grey lines in (a) show the depth minimum (canyon floor) and maximum (canyon  
 1160 crest) seafloor depth within  $0.5^\circ$  latitude of the microstructure profiles. In (b), zonal distance  
 1161 along the PGCM section has been converted to an equivalent longitude at  $25^\circ\text{S}$  so that length  
 1162 scales can be directly compared between the two panels. . . . . 66

1163 **Fig. 12.** (a-d) Watermass transformations at all abyssal depths and (e,f) buoyancy flux convergence  
 1164 at 3250 m depth in similarly-sized domains containing mid-ocean ridges, as diagnosed from  
 1165 (a,e) the PGCM-REAL simulation and estimated for the (b,f) Pacific, (c,f) Atlantic, and  
 1166 (d,f) Indian Oceans. In (a-d), the black, red, and blue lines show the net, bottom boundary  
 1167 layer (BBL), and stratified mixing layer (SML) contributions to the watermass transfor-  
 1168 mations, respectively (grey shaded indicates depths representing very little ocean volume). The  
 1169 black boxes in (e,f) delineate the similarly-sized regions (each with dimensions of roughly  
 1170  $3000\text{ km} \times 3000\text{ km}$ ) for which we compute the watermass transformations. In (e,f), red and  
 1171 blue show regions of buoyancy flux convergence (positive buoyancy tendency) and buoy-  
 1172 ancy flux divergence (negative buoyancy tendency), respectively. . . . . 67

1173 **Fig. 13.** Comparison of abyssal upwelling diagnostics in the PGCM-REAL simulation for the water-  
 1174 mass transformation analysis region highlighted in Figure 2a. The orange and blue lines in  
 1175 panel (d) represent the left- and right-hand sides, respectively, of the horizontally-averaged  
 1176 advection-diffusion balance  $\langle w \rangle A \simeq \langle N^2 \rangle^{-1} \frac{d}{dz} [A(z) \langle \kappa \rangle \langle N^2 \rangle]$  (eq. 24), which accounts for  
 1177 changes in isobath surface area  $A(z)$  with depth but ignores correlations between  $w$ ,  $\kappa$ , and  
 1178  $N^2$  and excludes the horizontal advection. The solid blue lines in panels (a), (b), and (c)  
 1179 show the individual components of the expressions: (a) the horizontally-averaged stratifica-  
 1180 tion  $\langle N^2 \rangle$ , (b) the horizontally-averaged buoyancy flux  $\langle \kappa \rangle \langle N^2 \rangle$ , and (c) the isobath surface  
 1181 area  $A(z)$ . The dashed line in (b) shows the role of correlation terms  $\langle \kappa N^2 \rangle - \langle \kappa \rangle \langle N^2 \rangle$  in  
 1182 setting the vertical structure of the buoyancy flux. Finally, the solid black line in (c) shows  
 1183 the net watermass transformation, where its native density coordinate has been mapped into  
 1184 a pseudo-depth coordinate by taking the average depth of a given buoyancy surface (eq. 19).  
 1185 For all of our simulations, vertical advection-diffusion bulk models are poor approximations  
 1186 of diapycnal abyssal upwelling. . . . . 68

1187 **Fig. 14.** Decomposition of the the watermass transformation into various physical components in the  
 1188 PGCM-REAL experiment (top row) and an experiment with a shorter ridge and constant refer-  
 1189 ence stratification (bottom row). In panels (a,c), we approximate the full watermass trans-  
 1190 formation (dashed black) by the contribution from the vertical buoyancy flux  $\partial_b (A \langle \kappa \partial_z b \rangle)$   
 1191 (solid black), which we then decompose into an uncorrelated component  $\partial_b (A \langle \kappa \rangle \langle \partial_z b \rangle)$   
 1192 (solid blue) and a residual  $\partial_b (A \langle \kappa' \partial_z b' \rangle)$  (solid orange), where  $\langle \cdot \rangle$  denotes averaging along  
 1193 a buoyancy surface. In panels (b,d), we further decompose the uncorrelated component into  
 1194 contributions due to the buoyancy derivative of the mean stratification  $\partial_b \langle \partial_z b \rangle$  (dashed) and  
 1195 the integrated diffusivity along a buoyancy surface  $\partial_b (A \langle \kappa \rangle)$  (dotted). . . . . 69

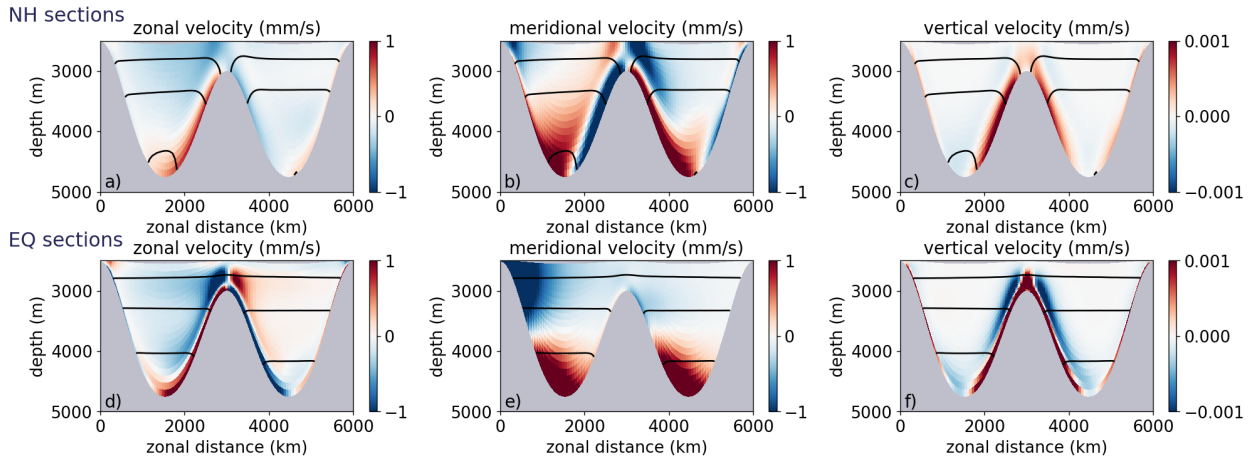

1196 FIG. 1. Schematic of a basin-scale abyssal circulation driven by near-boundary mixing. Dense bottom waters  
 1197 flow northward out of the Southern Ocean via a deep western boundary current (red circle) along the smooth and  
 1198 relatively quiescent continental slope, where little watermass transformation occurs. A cross-basin zonal flow  
 1199 feeds bottom waters from the deep western boundary current into a system of abyssal mixing layers driven by  
 1200 bottom-enhanced turbulent mixing over the rough topography of the mid-ocean ridge flanks (squiggly orange  
 1201 arrows). The turbulent buoyancy flux converges in a bottom boundary layer (BBL), driving vigorous diabatic  
 1202 upwelling across buoyancy surfaces (grey lines). In a stratified mixing layer (SML) above, the buoyancy flux  
 1203 diverges, driving diabatic downwelling. The net effect of the up- and down-welling in the abyssal mixing layers  
 1204 is a net transformation (dashed arrows) of bottom waters into deep waters. The newly formed deep waters return  
 1205 via cross-basin zonal flows to the smooth continental slope, wherein they flow southward in a deep western  
 1206 boundary current (blue circles) to close the abyssal circulation in the Southern Ocean. For simplicity, we omit  
 1207 the alternating along-flank flows (see Figure 3b) that are in frictional thermal-wind balance with the plunging  
 1208 isopycnals.

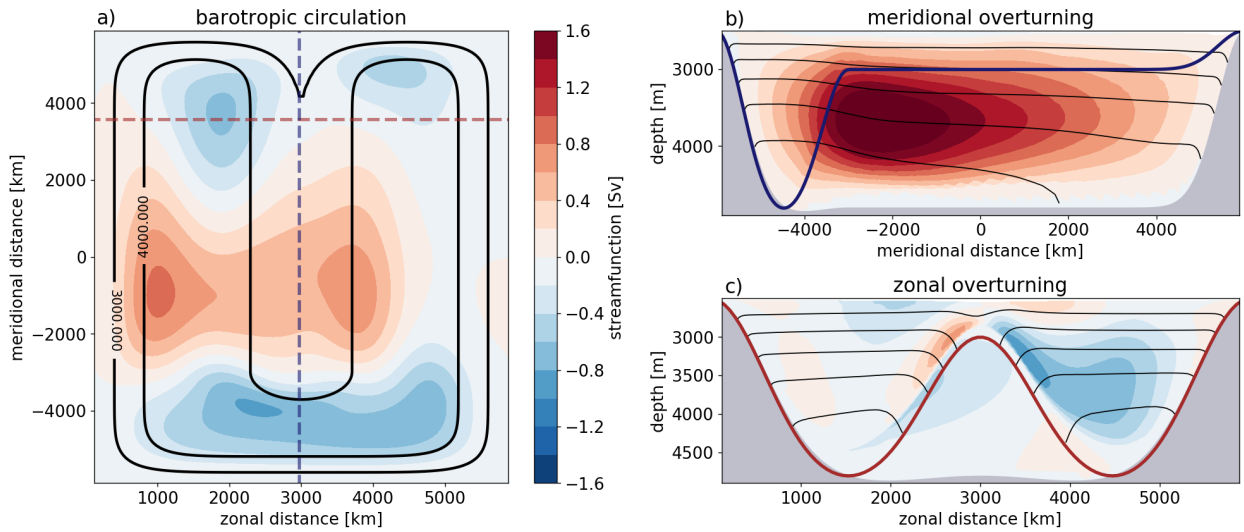

1209 FIG. 2. Configuration of the Planetary Geostrophic Circulation Model (PGCM). (a) Seafloor depth in the  
 1210 PGCM. We highlight the southern restoring region where we apply a buoyancy restoring which acts to transform  
 1211 deep waters into bottom waters (see Section 3c) and a northern-hemisphere region in which we diagnose wa-  
 1212 termass transformations along the mid-ocean ridge (see Section 4c). (b) Zonal section of the imposed turbulent  
 1213 diffusivity  $\kappa$ , which is bottom-enhanced over the mid-ocean ridge. (c) The red lines show the four stratification  
 1214 profiles  $B_z$  used in the PGCM as both the initial condition and as the reference profile for buoyancy restoring  
 1215 in the southern restoring region. The black line shows the observed stratification profile from the World Ocean  
 1216 Circulation Experiment (Gouretski and Koltermann 2004) in the South Pacific, averaged horizontally from 55°S  
 1217 to 45°S and 175°E to 115°W.

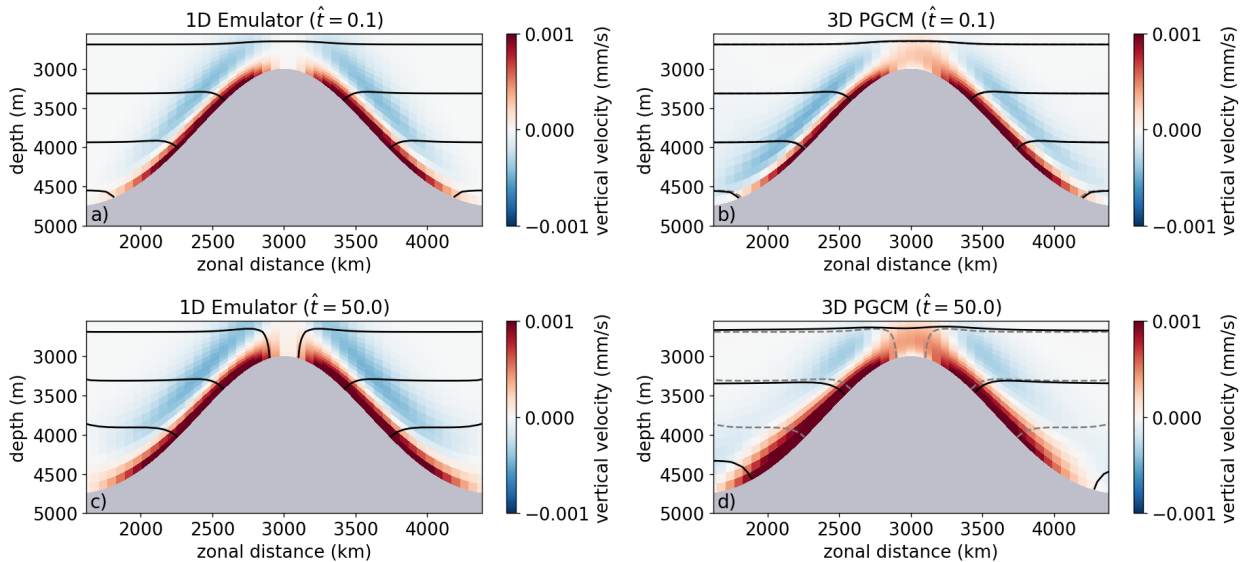

1218 FIG. 3. Cartesian components of the velocity vector in the PGCM-REAL simulation along: (a-c) a mid-  
 1219 latitude section in the northern hemisphere,  $y = 3000$  km, and (d-f) a section at the equator,  $y = 0$  km. Black  
 1220 lines show three equally spaced buoyancy surfaces.

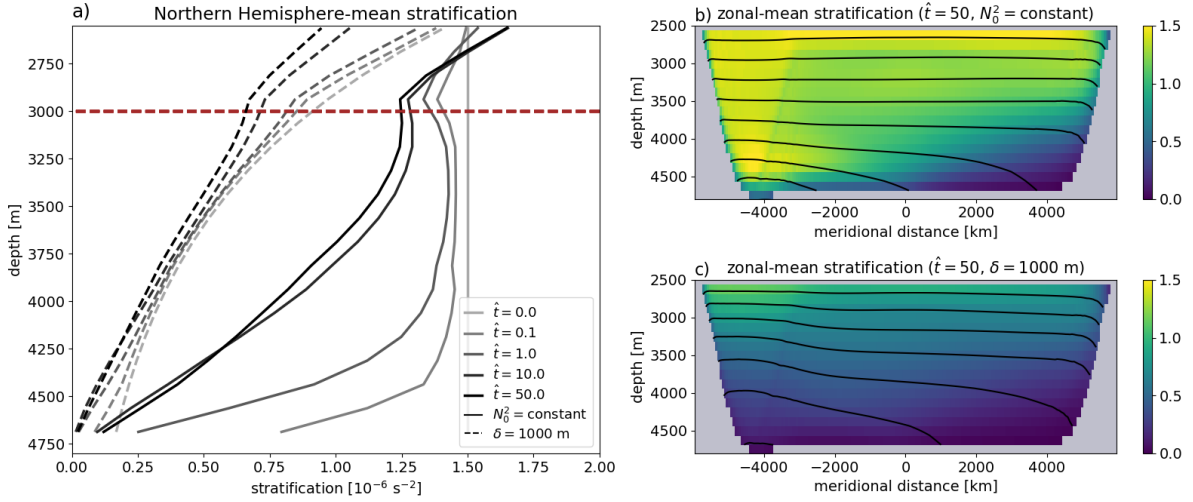

1221 FIG. 4. (a) Barotropic, (b) meridional, and (c) zonal overturning circulations in the PGCM-REAL simulation  
 1222 (see definitions in Section 4b). In all cases, positive values (red) correspond to counter-clockwise circulations.  
 1223 The red and blue solid lines in (b) and (c), respectively, show the height of the mid-ocean ridge along the dashed  
 1224 lines of the same colors in (a). The thick black lines in (a) are the 3000 m and 4000 m isobaths, which highlight  
 1225 both the continental slopes and the mid-ocean ridge. The thin black lines in (b) and (c) are equally-spaced  
 1226 buoyancy surfaces, sampled at  $x = L/4$  and  $y = L/2$ , respectively.

1227 FIG. 5. Watermass transformations from the PGCM-REAL simulation in (a) the full northern hemisphere  
 1228 basin ( $y > 0$ ), (b) along the northern-hemisphere mid-ocean ridge ( $y > 0, L/2 < x < 3L/2$ ), and (c) in a limited  
 1229 watermass analysis region along the northern-hemisphere mid-ocean ridge ( $0 < y < L/2, L/2 < x < 3L/2$ )  
 1230 highlighted in Figure 2. The black line shows the net watermass transformation, defined by equation (18). The  
 1231 red and blue lines show the contributions from the bottom boundary layer (BBL) and the stratified mixing layer  
 1232 above (SML). The dashed lines show the contributions from only the vertical component of the buoyancy flux.  
 1233 All watermass transformations in the paper are computed in buoyancy space and remapped into depth space  
 1234 (according to eq. 19).

1235 FIG. 6. Vertical velocity (colors) and buoyancy surfaces (black lines) in abyssal mixing layers along a zonal  
 1236 section at  $y = L/2$  that crosses the mid-ocean ridge in (a,c) the 1D PGCM emulator and (b,d) the full 3D PGCM,  
 1237 where both are initialized from identical constant stratification buoyancy fields. The top row shows the solutions  
 1238 at an initial time  $\hat{t} = 0.1$ , at which point the abyssal mixing layers have spun up but the basin-scale circulation has  
 1239 not (see Section 3d). The bottom row shows the solution at  $\hat{t} = 50$ , at which point the full solution has roughly  
 1240 come to equilibrium with the buoyancy restoring in the Southern Ocean. The predicted buoyancy surfaces in  
 1241 (a,c) are reproduced as dashed grey lines in (b,d) to show how the 1D emulator predicts the buoyancy field well  
 1242 for short times but that the interior stratification in the PGCM drifts far from the 1D emulator's prediction as it  
 1243 approaches equilibrium.

1244 FIG. 7. (a) Temporal evolution and (b,c) meridional structure of the stratification in PGCM simulations. Grey-  
 1245 scale lines in (a) show the temporal evolution of the horizontal-mean stratification in the Northern Hemisphere  
 1246 for simulations with a constant stratification restoring buoyancy profile (solid lines) and a restoring buoyancy  
 1247 profile corresponding to stratification that decays with depth with a scale height of  $\delta = 1000 \text{ m}$  (dashed lines).  
 1248 The dashed brown line delineates the height of the ridge crest. Panels (b) and (c) show the zonal-mean stratifi-  
 1249 cation at equilibrium  $\hat{t} = 50$  (colors) and equally-spaced buoyancy surfaces (black lines) for experiments with  
 1250 restoring to constant and exponential stratification, respectively.

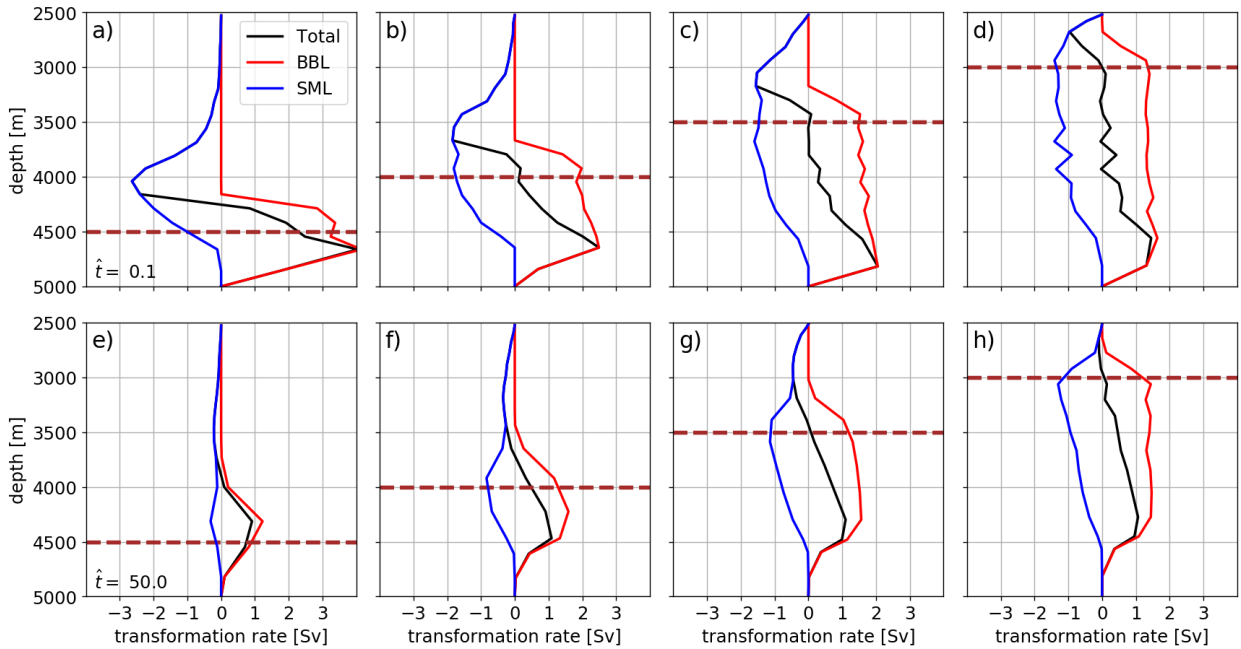

1251 FIG. 8. Watermass transformations in: (a, e) a 1D emulator of the PGCM and (b-d, f-h) the 3D PGCM  
 1252 simulations with restoring buoyancy profiles corresponding to stratification profiles with various exponential  
 1253 scale heights  $\delta$  (we recover  $N^2 = \text{constant}$  as  $\delta \rightarrow \infty$ ). The initial spin-up at  $\hat{t} = 0.1$  is shown in (a-d) and the  
 1254 equilibrium state at  $\hat{t} = 50$  is shown in (e-h). Black, red, and blue lines show the net, bottom boundary layer  
 1255 (BBL), and stratified mixing layer (SML) contributions to the watermass transformations, respectively. The  
 1256 black dashed line in (a,e) shows the integral constraint  $L\Psi_\infty = L\kappa_{\text{bg}} \cot \theta_{\text{max}}$  derived from boundary layer theory,  
 1257 where we take  $\theta_{\text{max}}$  as the maximum slope angle of the mid-ocean ridge flank.

1258 FIG. 9. Scaling of watermass transformations in mixing layers with (a) the height  $\delta$  over which the restoring  
 1259 stratification varies and (b) the bottom diffusivity  $\kappa_{bot}$ . Colored symbols represent the absolute value of the  
 1260 maximum transport in the BBL (red), the SML (blue), and the net (black), with squares and diamonds repre-  
 1261 senting the PGCM-CONST and PGCM-REAL simulations, respectively. The grey shading in (a) represents  
 1262 realistic vertical scales  $\delta$  over which abyssal stratification varies and in (b) represents plausible values of the  
 1263 bottom diffusivity  $\kappa_{bot}$ . Panel (c) provides an example of the watermass transformations for a bottom diffusivity  
 1264  $\kappa_{bot} = 5 \times 10^{-3} \text{ m}^2\text{s}^{-1}$ , a stratification height scale  $\delta = 1000 \text{ m}$ , and a ridge height of  $r_h = 1500 \text{ m}$ , where the  
 1265 corresponding maxima are marked by diamonds and the dashed brown line represents the ridge crest. In all  
 1266 experiments, the maximum net and BBL transformations occur at depths of roughly 4250 m, at the base of the  
 1267 ridge slope, while the maximum SML transformation occurs at the ridge crest.

1268 FIG. 10. Watermass transformations in PGCM simulations as a function of ridge height. All panels are for a  
 1269 fixed constant stratification restoring buoyancy profile. The initial spin-up at  $\hat{t} = 0.1$  is shown in (a-d) and the  
 1270 equilibrium state at  $\hat{t} = 50$  is shown in (e-h). Mid-ocean ridge height increases in increments of 500 m from left  
 1271 to right, as indicated by the dashed brown lines. Black, red, and blue lines show the net, bottom boundary layer  
 1272 (BBL), and stratified mixing layer (SML) contributions to the watermass transformations, respectively.

1273 FIG. 11. Diabatic zonal overturning circulation driven by bottom-enhanced mixing on the western flank of  
 1274 a mid-ocean ridge in (a) the South Atlantic Ocean and (b) the PGCM-REAL simulation. White lines show  
 1275 arbitrarily chosen contours of the counter-clockwise zonal overturning streamfunction, where the values for (a)  
 1276 are digitized from Figure 14 of St. Laurent et al. (2001) and for (b) are diagnosed from PGCM-REAL simulation.  
 1277 Coloring shows the vertical diffusivity in log-scale (light-grey shading represents depths with no microstructure  
 1278 measurements and does not necessarily represent topography), where panel (a) is inspired by Figure 2 of Polzin  
 1279 et al. (1997) and the diffusivity is calculated with microstructure profiles from the BBTRE experiment (Polzin  
 1280 et al. 1997; St. Laurent et al. 2001, archived at microstructure.ucsd.edu). Black lines are: (a) potential density  
 1281  $\sigma_4$  surfaces (referenced to 4000 m) from the microstructure profiles and (b) buoyancy surfaces from the PGCM  
 1282 solution, chosen arbitrarily to show that the zonal overturning circulation is indeed diabatic. The dark grey lines  
 1283 in (a) show the depth minimum (canyon floor) and maximum (canyon crest) seafloor depth within  $0.5^\circ$  latitude  
 1284 of the microstructure profiles. In (b), zonal distance along the PGCM section has been converted to an equivalent  
 1285 longitude at  $25^\circ\text{S}$  so that length scales can be directly compared between the two panels.

1286 FIG. 12. (a-d) Watermass transformations at all abyssal depths and (e,f) buoyancy flux convergence at 3250 m  
 1287 depth in similarly-sized domains containing mid-ocean ridges, as diagnosed from (a,e) the PGCM-REAL simu-  
 1288 lation and estimated for the (b,f) Pacific, (c,f) Atlantic, and (d,f) Indian Oceans. In (a-d), the black, red, and blue  
 1289 lines show the net, bottom boundary layer (BBL), and stratified mixing layer (SML) contributions to the wa-  
 1290 termass transformations, respectively (grey shaded indicates depths representing very little ocean volume). The  
 1291 black boxes in (e,f) delineate the similarly-sized regions (each with dimensions of roughly  $3000 \text{ km} \times 3000 \text{ km}$ )  
 1292 for which we compute the watermass transformations. In (e,f), red and blue show regions of buoyancy flux  
 1293 convergence (positive buoyancy tendency) and buoyancy flux divergence (negative buoyancy tendency), respec-  
 1294 tively.

1295 FIG. 13. Comparison of abyssal upwelling diagnostics in the PGCM-REAL simulation for the water-  
 1296 mass transformation analysis region highlighted in Figure 2a. The orange and blue lines in panel (d) rep-  
 1297 resent the left- and right-hand sides, respectively, of the horizontally-averaged advection-diffusion balance  
 1298  $\langle w \rangle A \simeq \langle N^2 \rangle^{-1} \frac{d}{dz} [A(z) \langle \kappa \rangle \langle N^2 \rangle]$  (eq. 24), which accounts for changes in isobath surface area  $A(z)$   
 1299 but ignores correlations between  $w$ ,  $\kappa$ , and  $N^2$  and excludes the horizontal advection. The solid blue lines in  
 1300 panels (a), (b), and (c) show the individual components of the expressions: (a) the horizontally-averaged strat-  
 1301 ification  $\langle N^2 \rangle$ , (b) the horizontally-averaged buoyancy flux  $\langle \kappa \rangle \langle N^2 \rangle$ , and (c) the isobath surface area  $A(z)$ . The  
 1302 dashed line in (b) shows the role of correlation terms  $\langle \kappa N^2 \rangle - \langle \kappa \rangle \langle N^2 \rangle$  in setting the vertical structure of the  
 1303 buoyancy flux. Finally, the solid black line in (c) shows the net watermass transformation, where its native den-  
 1304 sity coordinate has been mapped into a pseudo-depth coordinate by taking the average depth of a given buoyancy  
 1305 surface (eq. 19). For all of our simulations, vertical advection-diffusion bulk models are poor approximations of  
 1306 diapycnal abyssal upwelling.

1307 FIG. 14. Decomposition of the the watermass transformation into various physical components in the PGCM-  
 1308 REAL experiment (top row) and an experiment with a shorter ridge and constant reference stratification (bottom  
 1309 row). In panels (a,c), we approximate the full watermass transformation (dashed black) by the contribution  
 1310 from the vertical buoyancy flux  $\partial_b(A\langle\kappa\partial_z b\rangle)$  (solid black), which we then decompose into an uncorrelated  
 1311 component  $\partial_b(A\langle\kappa\rangle\langle\partial_z b\rangle)$  (solid blue) and a residual  $\partial_b(A\langle\kappa'\partial_z b'\rangle)$  (solid orange), where  $\langle\cdot\rangle$  denotes averaging  
 1312 along a buoyancy surface. In panels (b,d), we further decompose the uncorrelated component into contributions  
 1313 due to the buoyancy derivative of the mean stratification  $\partial_b\langle\partial_z b\rangle$  (dashed) and the integrated diffusivity along a  
 1314 buoyancy surface  $\partial_b(A\langle\kappa\rangle)$  (dotted).
