Abstract

The distribution of land and ocean on Earth's surface shapes the global atmospheric circulation and climate by modulating fluxes of water and energy between the surface and the atmosphere. Here we rearranged land in an idealized climate model to explore the effect

of eight simplified continental configurations on global climate, finding several counterintuitive results. The limited capacity of land to hold water and the smaller heat capacity of land compared to ocean—rather than surface albedo differences—are the primary drivers of continental control on global mean temperature. Specifically, the presence of land in certain locations can enhance tropospheric water vapor content, increasing the greenhouse effect and clear-sky shortwave absorption; these effects can warm the planet more than the cooling effect of higher land surface albedos. For example, continental configurations with land in polar regions and large tropical oceans have the warmest, wettest global climates. Configurations with large tropical land masses are not hot desert planets, but have the coolest global climates due to reduced evaporation and thus reduced atmospheric water vapor compared to configurations without land in the tropics. Interactions between the small heat capacity of land and the seasonal cycle can lead to certain continental configurations having even warmer, wetter atmospheres than an aquaplanet. Our results demonstrate that different configurations of land, such as those obtained through past tectonic movement or on rocky exoplanets, set planetary climate through mechanisms beyond those involving surface albedo or orographic effects.

Keywords: Water Vapor, Climate, Continents, Land-atmosphere Interactions

1 Introduction

The distribution of continents on Earth's surface alters both terrestrial and global climate in myriad ways: by modulating surface-atmosphere exchange of water and energy, shaping atmospheric circulation patterns, and delineating ocean basins. Despite its importance, the fundamental role of continental distribution in setting Earth's base-state climate remains poorly understood. In this study, we explore how the distribution of land on Earth's surface alters global evaporation patterns and water vapor concentrations, with implications for global mean surface temperatures and climate.

Physical differences between the land and the oceans alter the way the overlying atmosphere interacts with either surface. The land tends to be brighter, drier, rougher, and have a lower heat capacity than the ocean (Budyko, 1961, 1969; Payne, 1972; Bonan, 2008; Jin et al, 2004; Wiscombe and Warren, 1980; Sud et al, 1988; Cess and Goldenberg, 1981; North et al, 1983). Oceans can redistribute energy in the climate system by moving heat laterally while the land cannot (Loft, 1918; Richardson, 1980; Ferrari and Ferreira, 2011). Additionally, while water for evaporation is effectively unlimited in the oceans, the availability of water for evaporation to the atmosphere varies widely over different land regions as a function of the local climate (Baldocchi et al, 1997). Terrestrial evaporation and the surface supply of water varies seasonally and behaves differently under different climates. Moreover, while the evaporation

from the ocean is governed by atmospheric inputs (i.e. wind speed and radiation), the evaporation from the land surface also varies with soil moisture and physical properties of soil and vegetation that provide resistance to terrestrial evaporation (Manabe, 1969; Bonan, 2008).

In slab ocean aquaplanet simulations, the organization of tropical rainfall, the location of the extratropical jet, and the strength of the Hadley circulation are all shown to be impacted by changes in atmospheric water vapor, sea surface temperature, and solar insolation (Kirtman and Shukla, 2000; Barsugli et al, 2005; Kang et al, 2008, 2009; Voigt et al, 2014). The influence of continental configuration on atmospheric water vapor remains largely unexplored; however, recent work has shown that changes in terrestrial evaporation can drastically alter global-scale climate by modifying the total amount of atmospheric water vapor, a strong greenhouse gas (Laguë et al, 2021). In addition, other aquaplanet studies with dynamical oceans illuminate the connection between the distribution of meridional boundaries in the ocean and meridional heat transport, demonstrating how different climates can develop as a result of continental distribution (Enderton and Marshall, 2009; Ferreira et al, 2010).

In the modern continental configuration, changes in land surface properties generate large changes in both surface climate and global-scale circulation (Shukla and Mintz, 1982; Charney et al, 1975; Davin et al, 2010; Laguë et al, 2019). Moreover, the complex orography of mountain ranges impacts atmospheric circulation and generates large climate impacts over both land and ocean regions (Queney, 1948; Eliassen and Palm, 1960; Manabe and Terpstra, 1974; Held, 1985; McFarlane, 1987; Held et al, 2002; Maroon et al, 2015; White et al, 2017). While this study focuses on the impact of continental distribution on temperatures, the impact of the location and size of continents on rainfall has been explored extensively in monsoon literature (Dirmeyer, 1998; Yasunari et al, 2006; Maroon and Frierson, 2016; Zhou and Xie, 2018; Hui and Bordoni, 2021). Continental extent also modulates the response of precipitation to reduced terrestrial evaporation (Pietschnig et al, 2021).

Idealized modelling studies have further explored how the distribution of land impacts temperature by allowing for albedo feedbacks (Barron et al, 1984) as well as by altering the rate of CO_2 weathering and thus the strength of the CO_2 greenhouse effect (Worsley and Kidder, 1991). Latitudinal variations in albedo are driven directly by land distribution and indirectly through impacts on clouds and sea-ice (Enderton and Marshall, 2009; Voigt et al, 2014). The temperature at each latitude is largely modulated by the meridional heat transport (Pierrehumbert, 2010). Previous theory argues that heat transports by both the atmosphere and ocean, in turn, are largely insensitive to details of the dynamics responsible for the transport of heat, but rather depend more strongly on the mean planetary albedo and the equator to pole albedo gradient (Stone, 1978; Enderton and Marshall, 2009) as well as the evaporation and condensation of water (Fajber and Kushner, 2021).

The role of land distribution in modulating global climate has implications for improving our understanding of climate in Earth's geologic past. Reconstructions of Earth's continental configuration over the last several hundred million years span a wide range of continental distributions, sometimes with land clustered into supercontinents, sometimes with land spread widely across the globe as in the modern era (Merdith et al, 2021). Simulations of paleoclimate include continental configurations vastly different to that of the modern world to study the transition between glacial and interglacial periods (Hoffman and Schrag, 2002; Hoffman et al, 2017; Voigt et al, 2012), mass extinction events (Penn et al, 2018), and climatic changes due to the opening and closing of oceanic gateways (Straume et al, 2020).

We also expect to see different land arrangements on other planets. The habitability of exoplanets is a topic of interest to the astrobiology community (Méndez et al, 2021). The search for planets in the habitable zone hinges on locating the distance from a star that would allow for the presence of liquid water on a planet (a liquid environment is an expected requirement for life and water is the most abundant, common liquid in the universe) (Baross et al, 2007). While it is common to find exoplanets within the habitable zone of a star (Burke et al, 2015), whether or not those planets are actually habitable is difficult to determine (Kite and Ford, 2018). Planets with a vast range of masses, sizes, and orbits have been detected (Seager, 2013), with an anticipated wide range of variability in atmospheric mass and composition; the surface properties of those planets further modulate the planet's habitability (Rushby et al, 2020). The presence of liquid water is often used to determine the habitability of a planet (Seager, 2013); however, the distribution of hospitable surface climates across a planet will depend on local surface climate.

In this study, we explore and compare the climates of eight Earth-like planets, which differ only in their continental configuration. Land differs from ocean in the simulations presented here in three key ways: it has a higher albedo; it has a smaller heat capacity; and it has a limited capacity to hold and evaporate water, with increased resistance to evaporation when the land is not saturated. These differences alter the fluxes of water and energy between the surface and the atmosphere over land vs. ocean, leading to changes in both local surface climate and global-scale climate.

We show that the distribution of continents exerts a fundamental control on global climate, even in a model without full representation of the differences between land and ocean. We investigate how the distribution of land and ocean alter planetary surface albedo, total absorbed shortwave radiation at the surface, atmospheric water vapor and the water vapor greenhouse effect, and atmospheric feedbacks resulting from differences in land vs. ocean heat capacity. We conclude with a discussion of the role of land in modulating the base-state climate of a planet, as well as the sensitivity of that climate to changes in terrestrial evaporation.

2 Methods

2.1 Model

In this study, we use Isca (Vallis et al, 2018), an idealized global circulation model (GCM) to explore the climate of an Earth-like planet with various idealized continental configurations. There is a seasonal cycle in insolation (23.439° obliquity, 0 eccentricity) over a 360-day year. All simulations have atmospheric CO_2 fixed at 300 ppm. The model is run using a T42 horizontal grid (∼2.8°) and 40 vertical levels.

The atmosphere uses moist dynamics and produces precipitation, but does not represent the radiative effects of clouds. Therefore, we set the surface albedo of both water and land to a higher value than in a model that represents clouds, allowing for a more reasonable planetary albedo at the top of the atmosphere (see below for more details). In the configuration of the model used here, there are no albedo feedbacks from snow on land or sea ice. The Rapid Radiative Transfer Model (RRTM) (Vallis et al, 2018; Clough et al, 2005; Mlawer et al, 1997) is used for atmospheric radiative transfer, and we use the Simple Betts-Miller convection scheme (Betts, 1986; Betts and Miller, 1986; Frierson, 2007).

Analysis is primarily conducted using the Python programming language (Van Rossum and Drake, 2009), particularly with the NumPy (Harris et al, 2020), SciPy (Virtanen et al, 2020), and xarray (Hoyer and Hamman, 2017) packages.

2.2 Experiments

We run eight simulations, ranging from an all-ocean (Aqua) to an all-land (LandWorld) planet (Fig. 1). For five of the simulations, 50% of the planet's surface is covered by different distributions of land, and ocean covers the remaining 50% of the surface. TropicsLand has a single large continent in a belt around the equator, from 30°S to 30°N, with two oceans over each polar cap. CapLand is the inverse of this, with two continents capping the poles to 30°N/S, and a single large tropical ocean. NorthLand has a single large continent covering the whole northern hemisphere of the planet. EastLand has a single large continent covering the planet from the south to north poles, but only from 0-180°E longitude. In MeshLand, gridcells alternate between land and ocean in a checker-board pattern. Each patch of land/ocean in MeshLand is a single gridcell (roughly 2.8°). All simulations except RealLand have no orography. The RealLand simulation uses a semi-realistic, simplified continental configuration with roughly 20% of the surface covered by land, and idealized orographic representations of the Tibetan Plateau and the Rocky Mountains. This continental configuration is a modified version of that in Saulière et al (2012), and is produced using Isca's idealized land generator function (Vallis et al, 2018).

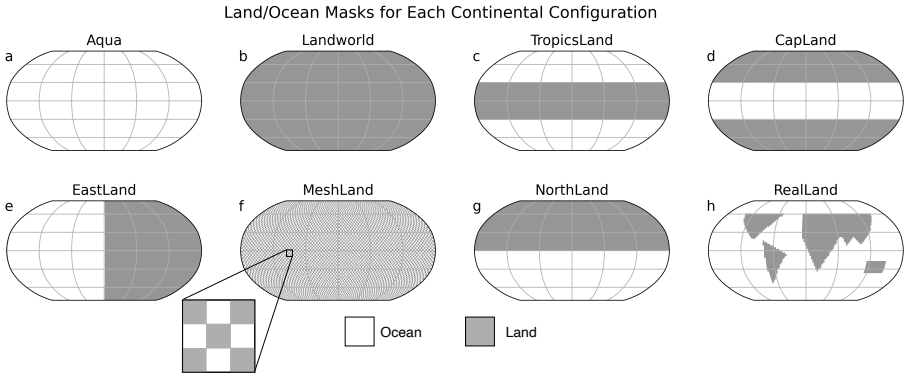

Fig. 1 Land/ocean masks for each continental configuration. Ocean is shown in white; land is shown in grey. A small section of MeshLand (f) is enlarged to show the land/ocean tiling pattern, where each tile is one gridcell (at roughly 2.8° resolution).

Land differs from ocean in these simulations through its albedo, smaller heat capacity, fixed capacity to hold water, and increased resistance to evaporation under dry soil conditions (table 1). In our simulations, land is 1.3 times brighter than the ocean; the ocean has an albedo of 0.25 and the land an albedo of 0.325. This is brighter than typical albedo values for ocean (Jin et al, 2004) and (snow-free) land (Bonan, 2008), allowing the model to generate similar global mean surface temperatures to our modern climate without the radiative effects of clouds, which increase planetary albedo (Herman et al, 1980).

Table 1 Surface properties of land vs. ocean in all simulations

	Albedo	Capacity to hold water [mm]	Heat capacity in equivalent water depth [m]
Ocean	0.25	Unlimitted	20
Land	0.325	150[1]	2

[1] Except in the LandWorld simulation, where water is allowed to accumulate beyond 150 mm.

The land can hold up to 150 mm of water at each point, with soil moisture represented by bucket hydrology. Land is initialized with 100 mm of water at every land gridcell. When the bucket is less than 3/4 full, the evaporative resistance of the land surface increases linearly as a function of soil dryness. When the bucket is more than 3/4 full, the resistance to evaporating water from the land surface is the same as that over open water. Water in excess of the bucket capacity is discarded as runoff; in effect, it is immediately returned to the ocean. However, in LandWorld there is no ocean for runoff to be discarded to, nor is there an oceanic water source to replenish the atmosphere with water; thus, discarding runoff would result in a system that does not conserve water. To address this, hydrology on LandWorld is modified to allow for the formation of lakes: water is allowed to accumulate in excess of the 150mm

bucket capacity, with the evaporative resistance the same as that of open water until the amount of water in the gridcell drops back below 150mm, at which point the standard bucket hydrology rules apply. The atmospheric circulation of LandWorld rapidly transports all of the available moisture to the polar regions where the land forms two "lakes" (see Laguë et al (2021) for discussion of the formation of polar lakes on an all-land planet). Note that despite the implementation of lakes in the LandWorld simulation, there is still a slow leak of water vapor from the atmosphere which causes the simulation to cool over time (Fig. A1); this is a known bug of Isca that is apparent in all-land configurations (see https://github.com/ExeClim/Isca/issues/177) and is not evident in the other simulations which can continuously replenish water vapor from the oceans.

The aerodynamic roughness of the land and ocean are the same in these simulations because the effects of surface roughness are outside the focus of this study. In reality, land is typically more aerodynamically rough than the ocean; the implications of this for climate are explored by past studies (Sud et al, 1988; Davin et al, 2010; Laguë et al, 2019).

The ocean is represented with a 20m deep mixed layer ocean that allows sea surface temperatures to evolve. No lateral heat transport is prescribed in these simulations. The heat capacity of the land surface in these simulations is 1/10 that of the ocean, and corresponds to that of a 2m deep mixed layer ocean, a larger value than the heat capacity of typical land surfaces on the modern Earth. The land and ocean heat capacities were selected based on previous Isca simulations that generate realistic climatologies (Thomson and Vallis, 2019; Geen et al, 2018).

Simulations are run for 20 years, with the first 4 years discarded to allow for model spin-up. After 4 years, global mean surface temperatures and average terrestrial soil moisture are stable for all simulations except LandWorld, which continues to lose water and cool throughout the length of the simulation (Fig. A1). Over the last decade of the LandWorld simulation, global mean temperatures decrease by roughly 1.5 K, but even without the water leak we expect this simulation to be cold and dry because the atmospheric circulation rapidly transports all the moisture to the polar regions where there is limited energy for evaporation.

3 Results & Discussion

3.1 Overview of scenarios

The eight different continental configurations considered here generate a wide variety of climates. The global average annual mean surface temperatures span almost 15 K (Fig. 2), ranging from the coldest global mean surface temperature on LandWorld (273.0 ($\pm$ 1.2) K) to the warmest global mean surface temperature closely shared among RealLand (286.7 ($\pm$ 0.03) K) and CapLand (286.5 ($\pm$ 0.1) K; numbers in brackets show $\pm$ the interannual standard deviation).

Table 2 Area in millions of km^2 (global and land-only) with annual mean temperature above 0°C ($T_{ANN} > 0$°C), and with annual mean precipitation above 300 mm/year ($P_{ANN} > 300$mm/year). Also shown is the % of the total land on each planet meeting these criteria, and the equator to pole temperature difference in K for each continental configuration (noted separately for the northern and southern hemispheres for NorthLand and RealLand, which are not symmetric about the equator).

Continental Configuration	Total Area with $T_{ANN} > 0°C$, in [km$^2 \times 10^6$]	Land Area with $T_{ANN} > 0°C$, in [km$^2 \times 10^6$]	% of Land Area with $T_{ANN} > 0°C$	Eq to Pole Δ T [K]	Total Area with $P_{ANN} > 300$ [mm/year], in [km$^2 \times 10^6$]	Land Area with $P_{ANN} > 300$ [mm/year], in [km$^2 \times 10^6$]	% of Land Area with $P_{ANN} > 300$ [mm/year]
Aqua	424	–	–	33	478	–	–
LandWorld	337	337	66	45	57	57	11
TropicsLand	378	260	100	34	273	64	25
CapLand	422	162	65	44	510	250	100
EastLand	396	193	76	43	322	85	33
MeshLand	416	205	80	36	492	244	96
NorthLand	406	188	74	46 (NH), 31 (SH)	432	189	74
RealLand	440	108	91	32 (NH), 29 (SH)	453	81	68

Over paleoclimate timescales, global mean temperatures are influenced by many factors, including changes in atmospheric CO_2 and ocean heat transport (Tierney et al, 2020). Our results show that continental distribution—independent of its impacts on CO_2 or ocean circulation—could be a potentially overlooked contributor to variations in past climate, as the range of surface temperatures generated solely by altering the continental arrangement and total amount of land produces changes in global mean surface temperature of the same order of magnitude as the temperature range experienced on Earth over the last 500 million years (Voosen, 2019).

The spatial distribution of surface temperatures varies between simulations (Fig. 2). The strongest equator-to-pole annual mean difference in surface temperature occurs over the continent in the NorthLand configuration, followed by LandWorld and CapLand, while the smallest equator-to-pole temperature difference occurs in both hemispheres of RealLand, followed by Aqua (Table 2).

Along with global temperature, the continental configurations also alter atmospheric circulation and global mean precipitation, with configurations with both more and less global mean rainfall than the modern Earth (Fig. 3). The highest global mean rain value occurs in the CapLand continental configuration (3.27 ± 0.01 mm/day), with the most rain falling over the tropical ocean. The lowest global mean precipitation values occur in Landworld (0.31 ± 0.16 mm/day).

All the continental configurations considered in this study can support liquid water, a common criteria for planetary habitability (Seager, 2013). However, the total area of land that would be hospitable to modern terrestrial ecosystems varies substantially across these continental configurations. To coarsely quantify the total land area in each simulation hospitable to modern day terrestrial ecosystems, we calculate the land area in each simulation with the annual mean temperature above freezing ($T_{ANN} > 0$°C). We also calculate the land area with annual mean precipitation above 300 mm/year ($P_{ANN} > 300$mm/year), which roughly marks the divide between arid and semi-arid ecosystems (Salem, 1989).

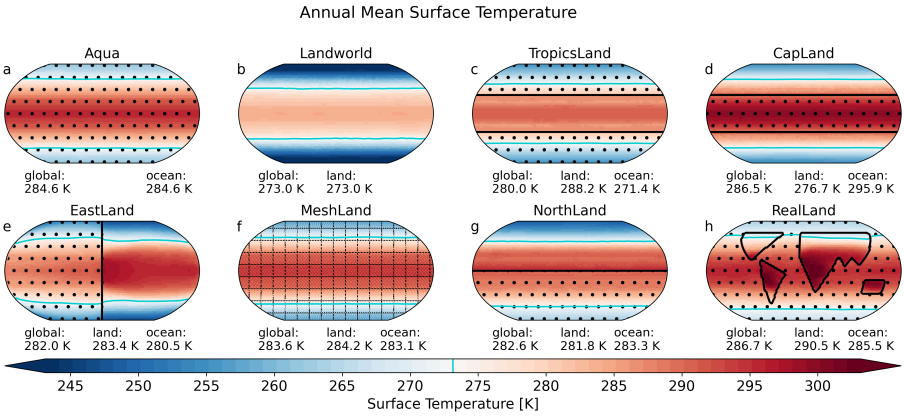

Fig. 2 Maps of annual mean surface temperature [K]. Ocean regions are stippled (except in MeshLand, where diagonal hatching is used to indicate the alternating land/ocean gridcells). Global, land-only, and ocean-only area-weighted annual mean values are noted below each map.

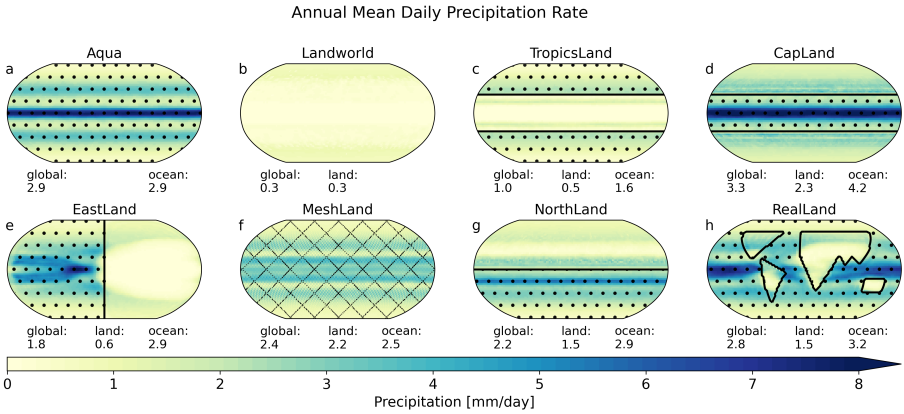

Fig. 3 Maps of annual mean precipitation [mm/day]. Ocean areas stippled (except in MeshLand, where diagonal hatching is used to indicate the alternating land/ocean gridcells). Global, land-only, and ocean-only area-weighted annual mean values are noted below each map.

The spread in the total land area with $T_{ANN} > 0$°C across simulations spans hundreds of millions of square kilometers (Table 2). RealLand has the smallest total land with $T_{ANN} > 0$°C, but it also has the smallest amount of land to begin with. Of the 50/50 land/ocean planets, CapLand and NorthLand have the smallest land area with $T_{ANN} > 0$°C, while TropicsLand and MeshLand have the most. LandWorld, which has the largest total land area, also has the largest amount of land above freezing in the annual average. However, both LandWorld and TropicsLand have large expanses of very dry land (Table 2). Indeed, only 11% of the land on LandWorld and 25% of the land on TropicsLand have $P_{ANN} > 300$mm/year. In contrast, 96% and 100% of

the land in MeshLand and CapLand (respectively) exceed the 300 mm/year precipitation threshold. Climate zone classifications provide a combined estimate of temperature and precipitation impacts on ecosystem distribution; Köppen-Geiger climate zones for each continental configuration explored here, calculated following Kottek et al (2006), are shown in Fig. A2.

In the sections below, we examine the main drivers of this wide spread in surface temperatures across the various continental arrangements, with particular focus on how land distribution impacts surface evaporation and atmospheric water vapor, the role of albedo, and feedbacks driven by differences in land vs. ocean heat capacity. The appendices contain figures showing transient and seasonal adjustments, meridionally resolved details, and additional fields of interest.

3.2 Association of water vapor and the greenhouse effect with surface temperatures

The various continental configurations explored here have a strong control on surface evaporation, and thus on the concentration of atmospheric water vapor. We find that the impact of the continental configuration on water vapor is the dominant control driving the spread of global mean surface temperatures across simulations, while differences in albedo and absorbed shortwave radiation play a secondary role.

Continental configurations that allow for the largest globally averaged latent heat flux (evaporation) produce the warmest global mean surface temperatures (Fig. 4a). This contrasts with the intuition of evaporative cooling leading to cooler surface temperatures. There is a strong linear relationship (r^2=0.87) between the global mean values of surface temperature and surface latent heat flux. Configurations with high surface latent heat flux have high total column water vapor (Fig. 4b). However, given the temperature-dependence of water's saturation vapor pressure, we must further explore this relationship to understand the cause and effect.

The total amount and spatial distribution of water vapor, a strong greenhouse gas, varies substantially across the continental configurations explored here (Figs. 4b, 5). All other greenhouse gases are prescribed to be identical across the simulations. We assess the effect of differences in water vapor concentration by approximating the strength of the greenhouse effect (following Kiehl and Trenberth (1997)) as the difference between longwave (LW) radiation emitted at the surface and emitted at the top of the atmosphere (TOA; equation 1):

$$LW_{diff} = LW^{\uparrow}_{surface} - LW^{\uparrow}_{TOA}. \quad (1)$$

Small values of LW_{diff} indicate a weak greenhouse effect while large values indicate a strong greenhouse effect.

Across the continental configurations tested, there are a wide variety of climate states that fall along a common line relating evaporation, water vapor, and surface temperatures. A strong linear correlation (r^2 = .82) exists across continental configurations between globally averaged latent heat flux and

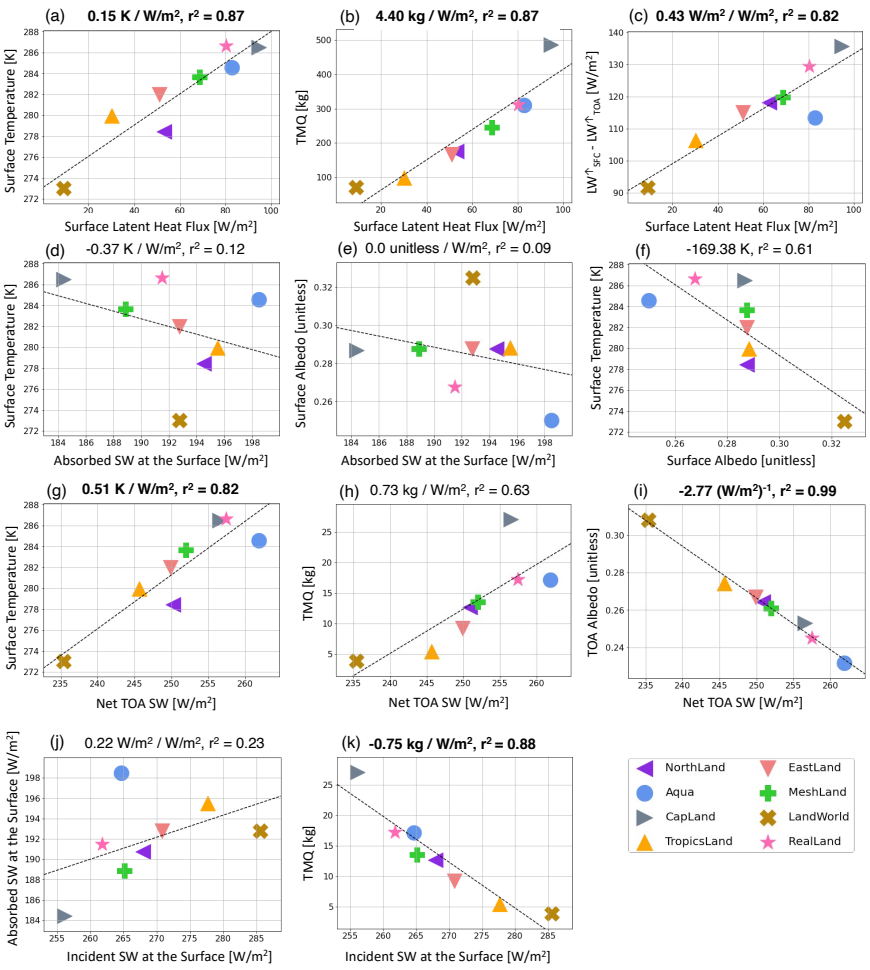

Fig. 4 Scatter plots showing the relationship between various global mean climate variables across the eight continental configurations. All values are shown for the annual mean, with each marker representing an individual continental configuration. The slope and r^2 value of a linear fit (dashed black line) is noted at the top of each panel, with slopes with a p-value < 0.05 shown in bold.

LW_{diff}, where configurations with high surface evaporation—and high water vapor (not shown)—have a stronger greenhouse effect (Fig. 4c). In the following sections, we discuss why each continental configuration leads to each distinct distribution of atmospheric water vapor and surface temperatures.

3.3 Surface albedo differences alone do not explain temperature spread

In our experimental planetary continental configurations, all planets that are 50% land and 50% ocean have the same globally averaged surface albedo. Yet,

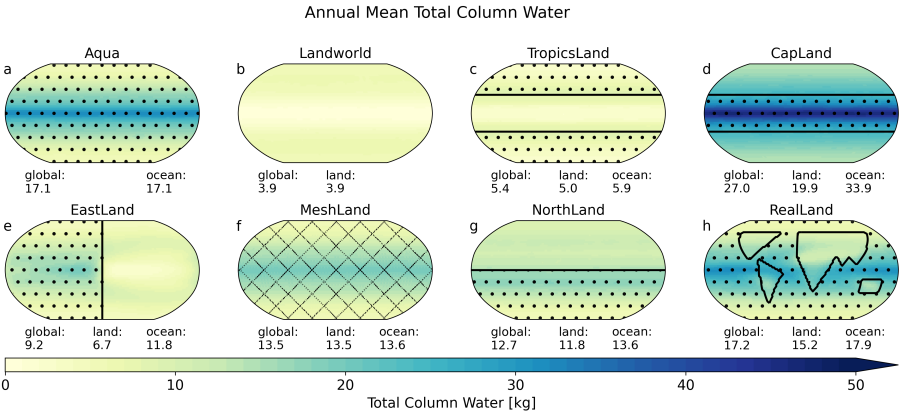

Fig. 5 Maps of climatological annual mean total atmospheric water vapor [kg] for each continental configuration. Ocean regions are indicated with black stipling, except in MeshLand where gridcells alternate between land and ocean (indicated by checkered hatching, which is not to scale with the model's grid). Global, land-only, and ocean-only area-weighted annual mean values are noted below each map.

for the five continental configurations that are half land and half water and thus with identical surface albedos, there is a roughly 10 K spread in global mean surface temperature (Fig. 4e-g).

Planets with more water (Aqua and RealLand) have an overall darker surface while LandWorld has an overall brighter surface. Surface albedo determines how much of the shortwave radiation energy reaching the surface is absorbed at the planetary surface, and can play a role in controlling surface temperatures by modulating the total amount of energy available to the land surface. Because the model we use does not represent the radiative effects of clouds, we might expect surface albedo to have a stronger impact on top of atmosphere albedo—and thus climate—than in the modern Earth. However, we still see a large spread in the TOA albedo (as shown by the net shortwave radiation flux at the TOA; Fig. 4i), resulting from changes in water vapor.

Along with the surface albedo, the amount of incident shortwave radiation in a region also modulates how much shortwave radiation is available for absorption at the surface. Given the absence of clouds in our simulations, one might hypothesize for simulations with darker ocean near the tropics and brighter land near the poles to absorb more shortwave radiation than simulations with bright land in the tropics since more shortwave radiation is incident at the top of the atmosphere in the tropics than in the high latitudes. However, we find simulations with bright tropical land masses, including TropicsLand and LandWorld, absorb relatively high amounts of shortwave radiation at the surface (Fig. 4d,e). This apparent discrepancy between surface albedo and absorbed shortwave radiation results from more shortwave radiation reaching the surface in configurations with tropical land (Fig. 4h). Water vapor impacts both shortwave and longwave radiative transfer through the atmosphere, and

larger amounts of shortwave radiation reach the surface in TropicsLand and LandWorld because the atmosphere is very dry.

Top of atmosphere albedo plays a central role in modulating global climate (Donohoe and Battisti, 2011). As our simulations do not have clouds, top of atmosphere albedo is instead a function of surface albedo and water vapor concentrations. The large differences in water vapor across our simulations generate a spread in TOA albedo even among simulations with the same globally averaged surface albedo (Fig. 4f; note that we plot absorbed SW at TOA as a proxy for TOA albedo because all models have identical insolation). There is a correlation ($r^2 = 0.82$) between the globally averaged TOA absorbed SW and global mean surface temperatures, with continental configurations which absorb more net SW radiation at the TOA being generally warmer than configurations which absorb less net SW radiation at the TOA. However, TOA albedo alone does not explain the full spread in surface temperatures across continenal configurations. For example, Aqua absorbs the most TOA SW (i.e. has the lowest TOA albedo), but both RealLand and CapLand are warmer.

Though the largest difference in surface albedo is between Aqua and LandWorld, their difference in globally averaged shortwave radiation absorbed at the surface is fairly small (Fig. 4e). That is, globally averaged surface albedo does not correlate well with globally averaged absorbed surface shortwave radiation. While the surface in LandWorld is much more reflective than the surface in Aqua, the dry atmosphere in LandWorld allows a larger amount of solar energy to reach the surface than the moist atmosphere of Aqua (Figs. 4j,k, 5b). Atmospheric water vapor both scatters and absorbs shortwave radiation (even in the absence of clouds), leading to less shortwave radiation incident upon the surface of Aqua than the surface of LandWorld.

For the 50/50 land/water planets, which all have the same surface albedo, there is about a 10 W/m^2 range in total absorbed shortwave radiation (SW) at the surface (Fig. 4e). RealLand, which has a smaller total land area, falls roughly in the middle of the spread. The reason for this non-intuitive relationship between global mean surface albedo and global mean absorbed shortwave radiation at the surface is the result of variations in incident shortwave radiation at the surface between continental configurations, which are due to differences in atmospheric water vapor concentrations. For example, CapLand absorbs a relatively small amount of globally averaged shortwave radiation despite the presence of dark ocean surface in the tropics. However, CapLand has a large concentration of atmospheric water vapor in the tropics (Fig. 5d) due to its tropical ocean. Because atmospheric water vapor scatters and absorbs shortwave radiation, there is less shortwave radiation incident upon the dark tropical surface in CapLand than there is in simulations with drier atmospheres, and thus less shortwave radiation is absorbed despite the dark tropical surface (Fig. 4j). TropicsLand, in comparison, has a much more reflective tropical surface than CapLand, but absorbs more total shortwave radiation because its dry atmosphere allows more solar energy to reach the surface than the humid atmosphere of CapLand.

Over sufficiently long timescales, the surface must balance the absorption of shortwave energy either by heating up (and thus removing energy from the surface as longwave radiation or sensible heat), or by evaporating water (removing energy from the surface as latent heat). For land, this occurs on comparatively short time scales due to its small heat capacity. The larger heat capacity of the ocean allows it to absorb more shortwave energy before that energy must be shed as latent heat, sensible heat, or longwave radiation. This difference in heat capacity plays a critical role in explaining why CapLand is both warmer and wetter than Aqua, which we discuss in section 3.6. In the real ocean, heat can also be transported by the ocean circulation, but our simulations have no ocean circulation by design. The sign of the relationship between the amount of shortwave radiation absorbed at the surface and the global mean surface temperature is the opposite of what one might naively expect: the warmest climates are those that absorb the least amount of SW radiation at the surface (Fig. 4d). Planets with less land (RealLand, Aqua) fall above this line, while the planet with more land (LandWorld) falls below this line.

LandWorld is colder than all the other continental configurations despite the large amount of absorbed SW at the surface (Fig. 4d). CapLand, RealLand, and Aqua span the full range of simulated globally mean absorbed shortwave at the surface, yet these three continental configurations are the 3 warmest planets, with similar global mean surface temperatures (roughly 285 K).

This disconnect between globally averaged surface albedo, absorbed SW at the surface, and surface temperature implies that we cannot rely on the surface albedo differences of land and water alone to explain the varied climates across continental configuration. These simulations do not allow for cloud effects on radiation; however, when cloud impacts on planetary albedo are taken into consideration for the modern Earth, surface albedo contributes only a small amount to the top of atmosphere albedo, which controls the total amount of energy absorbed by the Earth system at any given location (Donohoe et al, 2013).

3.4 Longitudinal distribution of land cools by limiting evaporation over the Eastland super-continent

The effect of continental arrangement on surface temperatures and climate through water vapor vs. albedo is further demonstrated in the comparison of MeshLand and EastLand. MeshLand and EastLand have the same amount of land at each latitude. As such, they have the same latitudinal distribution of surface albedo (or, equivalently, the same insolation-weighted surface albedo). We find that differences in water vapor driven by differences in evaporation are the dominant control making MeshLand a warmer planet than EastLand.

Despite MeshLand and EastLand having the same latitudinal distribution of surface albedo, there is more shortwave radiation incident upon the surface in Eastland, so more shortwave radiation is absorbed at the surface of EastLand compared to Meshland (Fig. 6). If this were the dominant control

on surface climate, we would expect EastLand to be warmer than MeshLand. Instead, we see that MeshLand is warmer; this is a result of differences in the strength of the water vapor greenhouse effect between the two continental configurations.

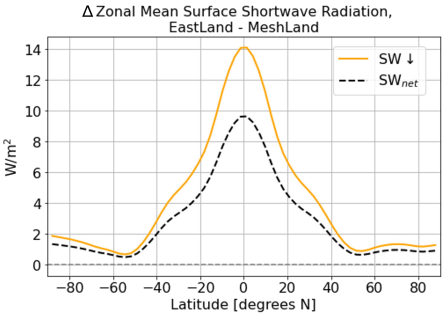

Fig. 6 Zonal mean, annually averaged difference in downwards (yellow) and net absorbed (black) shortwave radiation at the surface for EastLand - MeshLand.

The atmosphere in MeshLand has easy access to water everywhere, as each land gridcell is adjacent to ocean. In contrast, the atmosphere over the continent in EastLand is quite dry (c.f. Fig. 5e,f and A3e,f), particularly in the tropics where moisture that is advected onto the continent quickly precipitates out (Fig. 3e). The humid atmosphere of MeshLand results in a strong water vapor greenhouse effect, which drives the warmer temperatures of MeshLand compared to EastLand. This difference in water vapor also explains the difference in incident shortwave radiation between the two simulations; however, as noted above, this difference in shortwave radiation is not the controlling factor on surface temperature differences between these simulations.

Each MeshLand "island" behaves most similarly to archipelagos like the Maritime Continent, where the surrounding ocean provides moisture and the islands provide vertical motion for rainfall (Kooperman et al, 2017). Meanwhile, the zonal extent of the super continent of EastLand limits the range of moisture transport for precipitation to the interior, similar to Earth's Asian continent (though more extreme). The resulting dry lands and overlying dry atmosphere of the EastLand super-continent cool the global climate.

In the idealized climate model used in these studies, there are no radiative effects of cloud cover. Cloud radiative effects are an important part of the climate system and can respond strongly to terrestrial processes (Cho et al, 2018; Sikma and Vilà-Guerau de Arellano, 2019; Laguë et al, 2019; Kim et al, 2020), but they also represent a large source of uncertainty (IPCC, 2013; Zelinka et al, 2017). While the radiative effects of clouds would play a role in the climate of all continental configurations considered here, they may be of particular importance in the comparison of MeshLand to EastLand. Specifically, we would expect MeshLand to be cloudy because its atmosphere has ample access to water everywhere and the smaller heat capacity of land would

result in larger sensible heat fluxes over the land than the neighbouring ocean patches. This combination of vertical motion from sensible heating from the land and a steady moisture supply from both the ocean and the wet land would be conducive to the formation of cloud cover along the land/ocean boundary. The entire planet of MeshLand is comprised of patchy islands—areas which, on the modern Earth, enhance regional convection, cloud cover, and precipitation (Cronin et al, 2015), such as occurs near the Maritime Continent.

The patchy nature of MeshLand's continental distribution, and the resulting surface heat fluxes, is also reminiscent of regions of patchy deforestation in the tropics. In the Amazon, deforestation on the scale of tens of km^2 has been shown to lead to increased cloud cover at the grass-forest boundary. This deforestation generates regional circulations driven by sensible heating over the relatively dry grassland and moisture flux from the relatively moist rainforest (Khanna and Medvigy, 2014). Further exploration of a MeshLand-like planet, potentially with land patches of varying size, in a model that allows for radiatively interactive cloud cover would be useful to explore the impact of coastal land on cloud formation at different latitudes.

Another process that strongly impacts cloud formation and precipitation over complex topography is orographic lift (Kirshbaum and Smith, 2009; Houze, 2012; Maroon et al, 2015). Elevated orography can drive circulations and alter free-tropospheric temperature and regional climate, but the physics of this are complex and interact strongly with surface albedo (Hu and Boos, 2017). With the exception of RealLand, which has a simplistic representation of some mountain ranges, orographic effects are not represented in these flatland simulations. Rather than exploring the orographic effects of continents on climate, here we are specifically focused on the differences in land vs. ocean heat capacity, albedo, and evaporative properties and their effect on climate.

3.5 Large tropical landmasses limit atmospheric water vapor

The coldest three simulations (LandWorld, Northland, and TropicsLand) all have relatively large amounts of tropical land cover. These simulations are colder than the others at most latitudes in the annual mean (Fig. 2 and A4). Even EastLand, in which half of the tropics are covered by land, is cooler and drier than the simulations with open water across the entire tropics. Land can affect the global water vapor concentration both through evaporation and by changing the saturation vapor pressure of the atmosphere through changes in air temperatures.

Albedo differences between land and ocean cannot explain why configurations with large tropical land masses are cooler than other configurations. As discussed in section 3.3, the total amount of shortwave radiation absorbed at the surface is similar between these three simulations, and is higher than any other planet except Aqua (Fig. 4). Low shortwave radiation absorption over the tropical continents doesn't explain the cooler global temperatures—thus we examine differences in evaporation between simulations.

Generally, land is a dryer surface with limited water holding capacity compared to the ocean, and so serves to limit evaporation over the continents. The evaporative demand of the atmosphere is high in the tropics because of the warmer tropospheric air driven by high insolation. When there is ocean in the tropics, this evaporative demand is supplied by an effectively infinite reservoir of surface water. However, when the tropics are covered with land, the water on the land is quickly evaporated. While some of this moisture initially rains onto the land surface, e.g. in a classic intertropical convergence zone that occupies a narrow range of latitudes, tropical moisture export events (e.g. see Knippertz and Wernli, 2010) move moisture off the tropical continent. Eventually the tropical land dries out except along the edges of the continent, which experience seasonal precipitation.

The large latitudinal extent of the continent (between 30 degrees N-S) inhibits near-surface atmospheric moisture transport into the continental interior from the polar oceans. That is, were the equatorial continent of a smaller latitudinal extent, the equatorward component of the trade winds would travel over ocean (evaporating water along the way) before making landfall, thus bringing moisture onto the continent. With a latitudinally wide tropical continent, the near-surface winds travelling equatorward lie over land, thus the air is much drier than if the wind was travelling over an ocean surface. This results in most of the TropicsLand continent being dry, which means the tropical atmosphere cannot evaporate a large amount of moisture from the surface, resulting in a dry tropical atmosphere (Fig. A5).

In the modern continental configuration, near-surface winds in the tropics move moisture equatorward. However, in TropicsLand, the subsiding branch of the Hadley cell doesn't extend beyond the polar edge of the continent except in local summer. A small amount of moisture is brought onto the continental edge in summer (Fig. A5), but for the most part, surface winds in the low latitudes in TropicsLand do not travel over the ocean surface and thus do not transport moisture equatorward. In equilibrium, the large tropical land masses considered in this study are very dry and serve as a cap to tropical evaporation (Fig. 7).

Limited evaporation also means less latent cooling of the land surface, which could warm these tropical continents. However, the reduction of the water vapor greenhouse effect causes the continents to stay cool year round. The atmosphere at all latitudes becomes depleted in atmospheric water vapor (Fig. 5, A3). Instead of the surface temperature rising without evaporation, the atmosphere, robbed of its main source of moisture by the land surface, drys out and drives surface cooling via a reduced greenhouse effect. The weak greenhouse effect from low atmospheric water vapor is evident in the smaller magnitude of downwelling LW radiation at the surface in TropicsLand, LandWorld, and over the continent in Northland (Fig. A6). The water vapor feedback that operates in response to an arbitrary radiative forcing is expected to further reduce surface temperatures, amplifying the cooling produced by the initial land-induced drying.

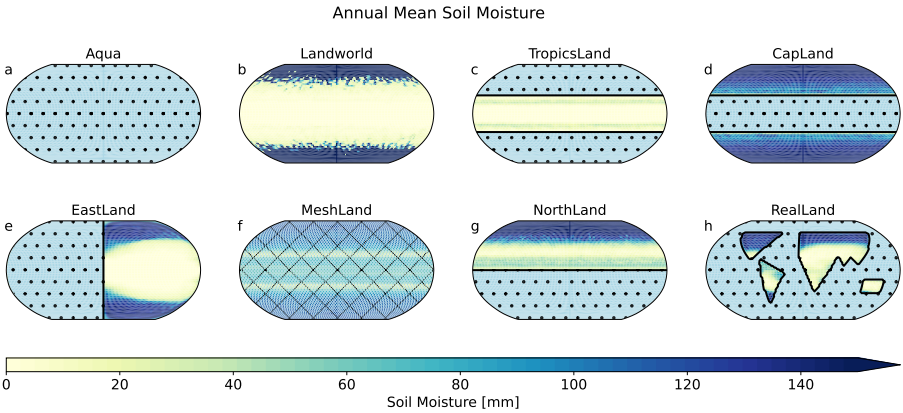

Fig. 7 Maps of annual mean soil moisture [mm]. Ocean areas are shown in light blue with stippling (except in MeshLand, where diagonal hatching instead of stippling indicates the alternating land/ocean gridcells). Note that all land regions have a maximum water-holding capacity of 150 mm except LandWorld, which has been modified to allow for lake formation to conserve water.

While there is ample water available for evaporation at higher latitudes—e.g. over the polar oceans in TropicsLand, from high-latitude soil moisture in NorthLand and Landworld, or from the southern hemisphere ocean in NorthLand—the lack of energy for evaporation at higher latitudes and horizontal mixing by the atmospheric circulation together maintain a dry tropical atmosphere in these simulations. The mid-to-high latitude atmosphere in TropicsLand does not contain nearly as much water vapor as the Aqua, CapLand, MeshLand, or RealLand continental configurations (Figs. 5 and A3). The southern hemisphere in NorthLand has much more water vapor than the northern hemisphere, which is consistent with the warmer surface temperatures of the southern hemisphere. The tradeoff between surface warming from reduced evaporation and large-scale surface cooling from a reduced atmospheric water vapor greenhouse effect is explored in detail for Northland in Laguë et al (2021).

The colder climates seen in our simulations with extensive tropical land cover may resemble Snowball Earth conditions, when tropical oceans were hidden beneath sea glaciers (Hoffman et al, 1998), or during past geological epochs when land was clustered into large tropical supercontinents (Chandler et al, 1992; Merdith et al, 2021). Though not explored here, we note that differences in ocean dynamics on paleoclimate timescales can also be large drivers of differences in climate even with approximately similar continental configurations (Chiang, 2009).

In addition to their dry atmospheres, the atmospheric circulations of LandWorld, TropicsLand, and NorthLand differ drastically from those of the other continental configurations. The meridional streamfunctions of the other continental configurations qualitatively resemble those of the modern Earth (Fig. 8).

However, for LandWorld, TropicsLand, and NorthLand, the dry tropical landmasses are highly depleted of soil moisture, and as such the tropical Hadley circulation is not dominated by moist dynamics, but rather by dry convection. The result is an overturning circulation which is vertically very short, and resembles the Hadley circulation expected for Snowball Earth (Voigt et al, 2012; Voigt, 2013) or the shallow meridional circulations over deserts (Zhai and Boos, 2017). In the case of NorthLand, this only applies to the northern hemisphere.

3.6 Land heat capacity drives a seasonally asymmetric feedback with evaporation and water vapor

In this section, we focus on the differences between CapLand and Aqua, to explain why a planet that is 50% land covered is warmer and has more atmospheric water vapor than an aquaplanet where the entire planetary surface is ocean. The open tropical oceans in Aqua and CapLand result in these two simulations experiencing the most total evaporation and atmospheric water vapor of all our simulations (Figs. 4, 5). Note that in terms of global mean surface temperature, these simulations are the closest analogs to RealLand, which also has high surface evaporation and total atmospheric water vapor compared to other continental configurations.

The dark tropical ocean surface with effectively unlimited water for evaporation results in a moist tropical atmosphere for both CapLand and Aqua. Initially, water evaporated over the lower latitude ocean falls as precipitation on the equatorial edge of the polar continents of CapLand before it is evaporated again and transported by transient eddies to higher latitudes. Atmospheric moisture transport in CapLand provides enough water to maintain high soil moisture all year long (Figs. 7 and A7). We note, however, that

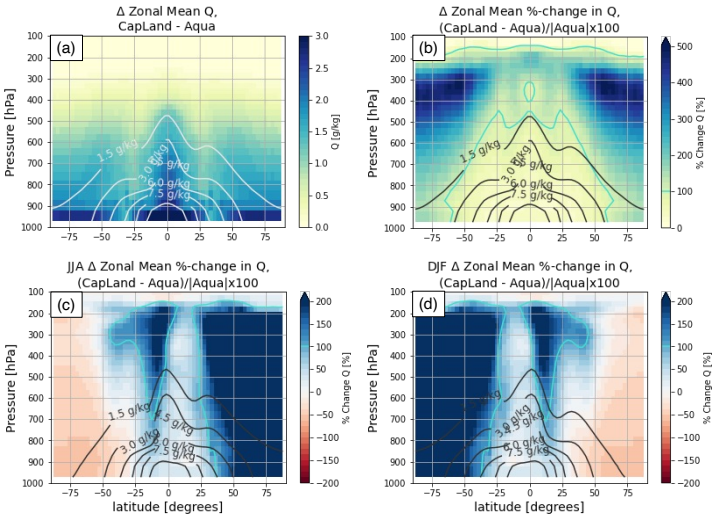

Fig. 9 Difference (CapLand – Aqua) in zonally averaged (a) annual mean specific humidity [g/kg] is shown in shading, with the climatological specific humidity [g/kg] from Aqua show in white contours. (b-c) show the percent change specific humidity for (b) the annual mean, (c) DJF, and (d) JJA in shading, with black contours showing climatological specific humidity [g/kg] from Aqua. Cyan contours in (b-d) show the 100% change in specific humidity line.

both CapLand and Aqua experience temperatures below freezing at the high latitudes during winter (Fig. A4), and thus we would expect the surface to be frozen for part of the year—but these simplified simulations do not account for the effects of sea ice or snow.

Despite its greater amount of land surface, CapLand is both warmer and has more atmospheric water vapor at all latitudes than Aqua (Fig. 9). This is particularly evident in the higher latitudes at higher levels of the troposphere, where the atmosphere in CapLand has over 100%—and in places in excess of 500%—more water vapor (in terms of specific humidity) than Aqua. While high soil moisture on the CapLand continents allows the surface to supply water to the atmosphere, the CapLand continent still differs from the high latitude ocean in Aqua in that it is brighter (higher albedo) and has a lower heat capacity.

The difference in both mean annual temperature and water vapor can be explained by the increased variation of seasonal temperature due to the land's lower heat capacity and a seasonal feedback through water vapor. Over land, the smaller heat capacity results in a larger seasonal amplitude of temperature than over ocean. CapLand has seasonally warmer local summers and cooler winters over the polar continent than over the oceans at the same latitude in Aqua (Fig. 10c,d). This increase in amplitude is expected; however, an increase in the annual mean temperature is not.

To explain the observed increase in mean temperature, we must consider two factors: (i) energy can be shed from the land surface not only as long-wave radiation (LW), but also as sensible heat (SH) or evaporation/latent heat

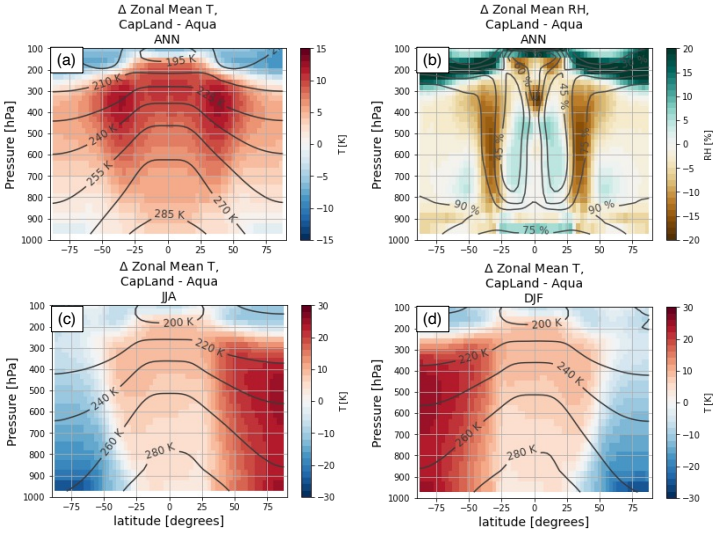

Fig. 10 Difference (CapLand – Aqua) in zonally averaged (a) annual mean air temperatures, (b) annual mean relative humidity, (c) DJF air temperatures and (d) JJA air temperatures, from the surface to 100 hPa. Contours show the climatological values for each field from the Aqua simulation.

(LH), and (ii) feedbacks due to water vapor through the greenhouse effect and atmospheric energy transport. The seasonal imbalance between the local winter and summer is a result of a feedback between surface evaporation and the water vapor greenhouse effect.

During local summer, there is an increase in the total amount of radiative energy flowing into the land surface (SW + LW) in CapLand (Fig. 11a-c). This energy is shed from the land surface through a combination of increased surface temperatures (as evident by increased $LW^{\uparrow}$ and SH), and increased surface evaporation (Fig. 11d-f). This leads to more atmospheric water vapor; because of the non-linearity of the Clausius Clapeyron relationship, the summer increase in specific humidity has a larger magnitude than the winter decrease (Fig. 9). Due to the increase in atmospheric water vapor during local summer, less incoming shortwave radiation reaches the surface (Fig. 11b). However, the increase in $LW^{\downarrow}$ into the surface is much larger than this decrease in $SW^{\downarrow}$ (Fig. 11a-c). The increase in $LW^{\downarrow}$ is a result of higher atmospheric temperatures and increased atmospheric water vapor, leading to a stronger greenhouse effect (which also helps to increase atmospheric temperatures).

Increased $LW^{\downarrow}$ into the surface adds energy into the land system, increasing the energy available for evaporation from the land. In CapLand, the soils remain wet through the summer (because of atmospheric moisture transport onto the continent; Figs. 7 and A7), supplying water to the hotter atmosphere and completing the feedback loop.

This evaporation-water vapor-greenhouse feedback is only possible *because* the continent in CapLand is very moist. Without available water on the polar

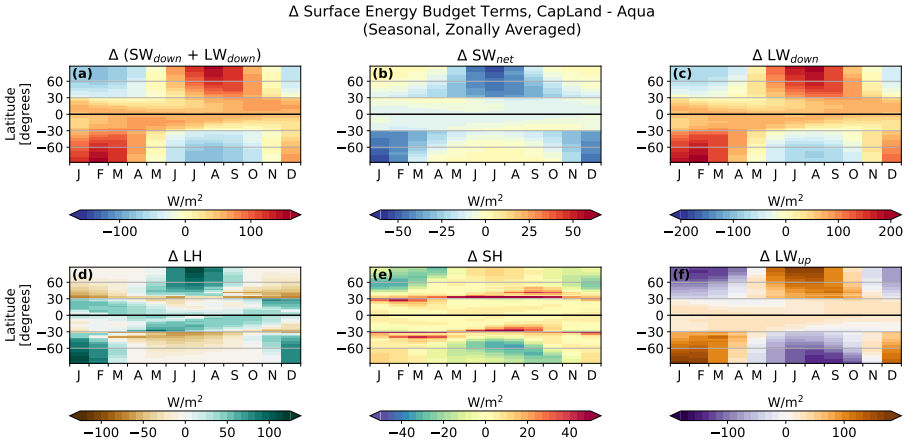

Fig. 11 Hovmoller plots showing the seasonal cycle of the difference in zonally averaged surface energy fluxes between CapLand and Aqua. The total radiative energy flux into the surface is shown in (a), separated into the net absorbed SW in (b) and the downwelling LW in (c). Panels d-f show the fluxes of energy leaving the surface, as latent heat flux (evaporation) in (d), sensible heat flux in (e), and emitted longwave radiation in (f). Note the difference in the scale of the color bars between panels.

continents, the small heat capacity of land would lead to warming but no change in evaporation rates in summer. In this hypothetical dry polar land scenario, the water vapor–greenhouse feedback would be much weaker or would not occur at all. The moist polar continents buffer the summer surface temperature response as excess energy from the strengthened greenhouse effect goes into evaporating more water rather than into warming the surface, which further strengthens the greenhouse effect. There is very little change in sensible heat flux at the surface between CapLand and Aqua, except right along the continental boundary (Fig. 11e).

The increased energy into the surface, increased evaporation, stronger water vapor greenhouse effect, and the resulting increase in energy into the surface are specific to summer, and create a seasonal imbalance in atmospheric air temperatures and atmospheric water vapor between summer and winter on CapLand vs. Aqua. The atmosphere over the continent in CapLand during local winter is slightly drier than the atmosphere over Aqua's ocean at the same latitude. In contrast, during local summer the atmosphere over CapLand is much more humid than the atmosphere over Aqua's ocean at the same latitude (Fig. 10). Concurrently, the magnitude of warming in summer is larger throughout the atmospheric column than the magnitude of cooling in winter. Only at low altitudes above the land surface is the winter cooling comparable to the summer warming in CapLand vs. Aqua (Figs. 10, 11f). The small heat capacity of land interacting with the seasonal cycle drives this feedback, which is why summer temperatures are amplified in CapLand vs. in Aqua. This summertime CapLand-specific feedback does not occur in winter because evaporation is low in both CapLand and Aqua.

The non-linear relationship between longwave radiation and surface temperature could also introduce seasonally asymmetric temperature responses, however in our simulations, this relationship fails to explain our results. If we were to assume that the difference in insolation between summer and winter must be removed from the land surface as longwave radiation through a change in surface temperature (i.e. ignoring sensible or latent heat flux) and that the change in insolation is equal and opposite in summer vs. winter, then by the Stefan–Boltzmann law ($LW \propto \sigma T^4$ (Stefan, 1879)), a *larger* change in surface temperature is needed during the cold season than is needed during the warm season in order to produce the same anomalous magnitude of longwave radiation. However, we do not find this in our simulations (Fig. 10c/d). Moreover, the critical difference in the CapLand vs. Aqua climate at high latitudes is the amplified amount of energy into the CapLand surface during local summer.

Past studies have explored similar idealized continental configurations to CapLand and TropicsLand, with opposing conclusions on which configuration makes for the warmer planet. Worsley and Kidder (1991) found that the tropical continental configuration allows for greater removal of CO_2 from the atmosphere through weathering and thus results in a cooler climate due to a diminished greenhouse effect. In contrast, Barron et al (1984) found the polar continental configuration generates the cooler climate as it provides a surface for high-latitude snow accumulation, which generates cooling through snow albedo feedbacks. In this study, we identify a third mechanism of importance: a planet with moist land capping the poles and a tropical ocean is warmer than the planet with a tropical land belt and polar oceans because the continental arrangement exerts strong controls on evaporation and atmospheric water vapor.

A critical difference between our simulations and those of Barron et al (1984) and Worsley and Kidder (1991) is our inclusion of a seasonal cycle. Without seasonality, the low heat capacity of land and the resulting summertime evaporation-water vapor-greenhouse effect feedback does not occur; this summertime warming feedback is the primary driver for our warmer CapLand simulation compared to Aqua. Moreover, our simulations do not allow for changing albedo from clouds, snow, or sea ice, nor changes in CO_2 due to weathering. Macdonald et al (2019) find arc-continent collisions in the low latitudes increase the removal of atmospheric CO_2 through intensified chemical weathering, a similar mechanism to that invoked by Worsley and Kidder (1991). However, the weathering mechanism requires the tropical continent to receive adequate moisture to allow for rock weathering. Yet our TropicsLand simulation provides a potential counterexample to this, where a large tropical land mass could have low weathering rates due to the dry atmosphere with limited precipitation. While we do not simulate rock weathering impacts on atmospheric CO_2 in our simulations, we would expect weathering rates to be lower over TropicsLand than, for example, MeshLand, which has much higher precipitation rates over land. That is, the intensity of weathering in the low

latitudes requires not only the presence of land, but also the presence of precipitation. However, if our tropical continent were smaller in extent, allowing for more atmospheric water vapor and precipitation, the potential for CO_2 removal from rock weathering would likely be higher.

4 Conclusions

The distribution of land exerts a first-order control on global climate by modulating atmospheric water vapor concentrations. The eight idealized continental configurations considered here produced climates that span a range of roughly 15 K in global mean surface temperatures. We find strong relationships between surface evaporation, surface temperatures, and total atmospheric water vapor across the simulations.

While the climate of each continental configuration considered here differs, the mechanisms controlling these climates share many commonalities; in particular, each includes a feedback with the greenhouse effect of water vapor. When large landmasses are positioned in high insolation areas like the tropics, as is the case with TropicsLand, LandWorld, NorthLand, and EastLand, we do not get hot desert worlds; instead, the relatively dry land leads to water vapor depletion and a relatively cool climate. Our modern continental configuration drives a climate that is among the warmest and wettest of the configurations explored here, which is consistent with our findings that continental configurations with large tropical ocean area have warm, moist atmospheres. While there is land at low latitudes on modern Earth, there is also extensive ocean area; the relatively wet atmosphere of RealLand suggests that the modern Earth continental configuration does not limit tropical evaporation or tropical atmospheric water vapor.

Also of great importance is the fact that the low heat capacity of a wet continent at the poles in CapLand creates a larger seasonal cycle of temperature and generates a seasonal evaporation/water vapor feedback that amplifies summer warming. This feedback creates a climate that is wetter and warmer on a planet with 50% land cover than on an aquaplanet without continents.

Our framework allows us to isolate a new mechanism through which tropical vs. extratropical land masses can modulate global-scale climate, and also highlights the importance of continental distribution for global climate through its influence on atmospheric water vapor. Further study is required to determine the combined climate effects of tropical vs. extratropical land on long-term atmospheric CO_2 concentrations, surface albedo (through snow cover), and top-of-atmosphere albedo (through cloud cover and water vapor effects). How much these various effects may amplify, damp, or generate interactions which could further feed back on global climate is necessary to understand the total impact of continental distribution on global-scale climate.

The different continental configurations explored here are idealizations, but provide possible analogues for past continental configurations (see Merdith et al (2021)), or configurations on different water-land planets. We show how

the distribution of land on a planet's surface has a fundamental control on surface climate by modulating atmospheric water vapor concentrations and creating feedbacks between heat capacity and the seasonal cycle, with variations in the distribution of a fixed amount of land across the planetary surface generating a substantial spread in global mean surface climate.
