Abstract
Researchers and engineers have increasingly used Deep Learning (DL) for a variety of Remote Sensing (RS) tasks. However, data from local observations or via ground truth is often quite limited for training DL models, especially when these models represent key socio-environmental problems, such as the monitoring of extreme, destructive climate events, biodiversity, and sudden changes in ecosystem states. Such cases, also known as small data problems, pose significant methodological challenges. This review summarises these challenges in the RS domain and the possibility of using emerging DL techniques to overcome them. We show that the small data problem is a common challenge across disciplines and scales that results in poor model generalisability and transferability, yet this has not been investigated in a structured way. We first introduce ten emerging DL techniques: transfer learning, self-supervised learning, semi-supervised learning, few-shot learning, zero-shot learning, active learning, weakly supervised learning, multitask learning, process-aware learning, and ensemble learning; we also include a validation technique known as spatial k-fold cross validation. These techniques have shown promising potential in other scientific disciplines, but have been rarely applied in the RS domain. We also provide guidance on which learning technique to use in various cases, which helps to create a more methodologically robust DL application (and a greater number of them) that can be used to tackle socially important problems with limited data.

Keywords: Small data problems, Remote sensing, Deep learning, Transfer learning, Few-shot learning, Zero-shot learning, Self-supervised learning

1. Introduction

Over the last decade, Artificial Intelligence (AI) technologies, especially Machine Learning (ML) and Deep Learning (DL), have been increasingly used for understanding and predicting human-
environment interactions (LeCun et al., 2015). ML is a subset of AI that implements algorithms which use data to learn how to perform a specific task without being explicitly programmed. DL is a subset of ML that focuses on training deep neural networks capable of implicit feature extraction from unstructured data, such as images, text, and sound (Chai et al., 2021; Lauriola et al., 2022; Sztahó et al., 2021). Scientists have actively employed DL for image processing and data analysis, recently providing innovative solutions in the field of Remote Sensing (RS) to detect and classify objects on Earth. This study defines RS as the use of satellite and aircraft-based sensors.

The expanding field of RS provides an abundance of data streams from numerous sources. This, combined with the growing array of available data products, delivers a wide range of data that is useful for addressing various problems. Among them, Landsat, has been operational since the early 1970s and provides a unique long-term record of satellite imagery with a 30-metre spatial resolution. The Copernicus programme’s Sentinel-2 system generates data with a 10-metre spatial resolution, offering a balance between spatial detail and data continuity as well as radar imagery based on the Sentinel-1 mission. One recently launched hyperspectral mission, the Environmental Mapping and Analysis Program (EnMap), stands out with over 200 spectral bands and a 30-metre spatial resolution; this offers unique opportunities for researchers to map ecosystems and their changes in detail. In addition, commercial platforms, such as SkySat, provide extremely high-resolution data with a spatial resolution of less than one metre (Fruth et al., 2018; Murthy et al., 2014). Together, these diverse RS platforms contribute to a more comprehensive understanding of the Earth’s surface across different scales and domains (Spoto et al., 2012). For this reason, these RS products are widely used to study local and regional environmental problems, including agricultural productivity (Sawada et al., 2020; Taiwo et al., 2023), the water quality of lakes and ponds (Bhateria and Jain, 2016), the ecological patterns of forests and grasslands (Zhu et al., 2023), and damage to natural, cultivated, and inhabited land through extreme weather events. Since the spatial and temporal resolution of RS products is likely to continue increasing, DL applications are expected to become even more popular for solving fine-scale local issues where each local site has its own unique conditions and context (T. Bai et al., 2022; Kattenborn et al., 2021; L. Ma et al., 2019).

Since DL algorithms have fewer inductive biases but larger parameter counts than conventional ML algorithms, DL models normally require a large amount of data for training (Adugna et al., 2022; Akar and Güngör, 2012; Fang et al., 2021; Sharma et al., 2013; Thanh Noi and Kappas, 2018). DL methods usually learn from raw data and skip manual feature engineering steps; this means that human efforts are not needed to quantitatively measure some attributes from the data. For example, DL algorithms can learn from image data directly, instead of using the extracted shape and size of an object in an image. When sufficient data is available, DL methods can automatically extract the meaningful features from low to high levels for prediction (C. Zhang et al., 2019). However, although raw data of common events is generally abundant, the lack of sufficient labelling information makes the collection and preparation of a large reference dataset
a persistent challenge for many RS applications. Moreover, certain scenarios also lack available reference data. For instance, biodiversity monitoring needs a large number of human observers well trained in taxonomic classification, which often prevents observation campaigns from generating datasets large enough for sound DL applications. Furthermore, anomaly events such as climate extremes and disease outbreaks are too rare for researchers to acquire sufficient data coverage. Their sample size is often as small as n = 1–300, which is usually insufficient for DL application (Kokol et al., 2022).

The gap between the large data availability of RS imagery and the small data (Brigato and Iocchi, 2020) availability of several important real-world environmental problems (referred to as the “small data problem”) is a very common challenge. It is hard to acquire the ground-truth response labels associated with the input features. This makes sense, because the goal of most of these studies is to develop a model designed to predict a specific response variable from the various observed input features. However, traditional DL training methodologies require a large initial set of labelled data to train predictive models. It is increasingly clear that this is an emerging problem for AI, and researchers have proposed several novel DL techniques that require less labelled data (e.g., transfer learning and self-supervised learning). However, to the best of our knowledge, the small data problem has not been systematically tackled as an emerging scientific challenge in the RS domain.

In this review, we summarise the current research on the small data problem in RS (particularly as it relates to DL) and suggest promising DL techniques to address this problem. First, we explore how the small data problem can be defined. Second, we describe a few common elements of the previous studies. Third, we present the advantages and disadvantages of using a small dataset. Finally, we offer a set of practical recommendations about how RS scientists can better implement DL techniques to fully make use of a small dataset. We believe that the small data problem is a common – but still unsolved – issue for recent RS applications, and therefore, this review should serve as a valuable resource for supporting RS and DL applications in scientists’ and policymakers’ attempts to address a wide range of environmental problems.

2. What is the small data problem?

We argue that a dataset can be considered large (not small) when the dataset consists of >100,000 annotated samples, or when it covers the entire probability distribution in a high-dimensional space. In this case, model generalisability and transferability are expected to be high. For example, there are several free large datasets that can be used for DL: the ImageNet dataset, containing over 14 million annotated images (Russakovsky et al., 2015), the Common Objects in Context (COCO) dataset, containing 330K images, 1.5 million object instances, and 80 object categories (Lin et al., 2015), and the OpenImages dataset, containing over 9 million images (Kuznetsova et al., 2020). These datasets can be used for training a large DL model.
with thousands to millions of parameters. In the RS domain, land use/land cover classification would be a typical example.

In contrast, data is more likely to be regarded as small (or not large enough) when the dataset consists of <1,000 annotated samples, the dataset covers the distribution poorly, or the number of samples is expected to be insufficient when using DL to find meaningful features. This is a frequently occurring situation, but it can be a significant challenge for training deep neural networks (Adadi, 2021; Du et al., 2019). A relatively small dataset can negatively affect the performance of a DL model due to overfitting, which is when a model performs well with the training data but poorly on new, independent testing data. This therefore results in low levels of model generalisability and transferability. A common case within the RS domain (but particularly relevant) is that the data can be “extra-small”, meaning that the dataset consists of just 1–10 annotated samples (e.g., historical natural disasters and disease outbreaks). The size would be sufficient for human beings to start guessing what features can uniquely describe the target, but it would not be sufficient for automated, implicit DL feature extraction.

In the DL domain, the Tiny ImageNet Dataset (also known as MicroImageNet) contains 500 images for each class (of 200 classes), indicating that DL scientists regard this level of data size as small. According to the articles we reviewed in the following section, the majority of the studies targeted classification of a few types, and many of them collected less than 500 images for each class (Blekos et al., 2020; Dyrmann et al., 2016; Freeman et al., 2019; Guirado et al., 2017; Hong-Yu et al., 2023; L. Li et al., 2022; Liu and Zheng, 2017; Z. Liu et al., 2022; Malambo et al., 2019; Pang et al., 2020; Putra and Wijayanto, 2023; Safonova et al., 2022, 2021, 2019; Sapkota et al., 2022; Windrim et al., 2019; Zenkl et al., 2022).

There should not be a strict divide between “small” and “large” when training DL models, because the size of the dataset required may depend on various factors such as the complexity of the task and the number of features in the data. Typically, the challenges stemming from a limited amount of labelled data increase with system complexity, the rarity of observations (e.g., endangered biological species), and the coverage of geographic area. Also, classification and detection problems may need less data than regression problems. Nevertheless, a convincing theoretical argument for separating the two could be made based on whether a trained DL model exhibits a “double descent”, which means that a model’s performance initially improves with increased complexity, worsens, and then improves again, contradicting the traditional expectations of a bias-variance trade off (Nakkiran et al., 2019). When the dataset is not large enough, the model tends to remember all possible case-by-case instances without generalisation (and thus overfit). However, once the dataset is large enough, the DL model starts learning a handful of general features (Elhage et al., 2022).

The small data problem may be relevant to the “small $n$, large $p$ ($n<p$)” problem in statistics, where the sample size $n$ is much smaller than the number of parameters $p$ (also known as the “short, fat data” problem). As a rule of thumb, each parameter can be reasonably estimated with $n = 5–10$. According to this
logic, it is then possible to estimate how many samples might be needed for a given DL model. Even one of the simplest convolutional neural network (CNN) architectures, LeNet-5 (two convolutional and three fully connected layers), still has about 60,000 parameters (Lecun et al., 1998). The most popular CNN architectures have 10 million to 100 million parameters (e.g., AlexNet, VGG, Inception, and ResNet), (Khan et al., 2020), and there is a trend towards increasing the number of parameters for achieving better performance (e.g., large language models). For instance, vision transformers (Dosovitskiy et al., 2021) have recently gained more and more traction, with some models consisting of more than 20 billion parameters (Dehghani et al., 2023).

3. Deep learning applications in RS with the small data problem

This section is a literature review describing how common the small data problem is in the RS domain. Initially, we made a Web of Science Core Collection search with the following keyword combination in the “all fields” category: {“remote sensing” AND (“deep learning” OR “convolutional neural” OR “recurrent neural”) AND (“small data” OR “small sample” OR “limited sample” OR “limited data”)}. We found 161 articles as of 18 January 2023. We first examined all titles and abstracts and discarded irrelevant articles. Moreover, we relied on snowball sampling of relevant papers from the reference lists of the literature that had not emerged via the systematic search but were relevant to the main goals of this review. This resulted in 80 additional articles. The list of articles with detailed information is available in Appendix A. Our approach may have omitted several articles that also addressed the small data problem, but the goal here was not to cover every single previous study. Instead, we have attempted to describe how broad the issue is, and such an effort may not be worthwhile, given the speed of scientific progress, where today’s comprehensiveness may be far less important in the next couple of years.
Figure 1. An overview of publication trends where studies use RS with a limited number of annotated data and DL (since 2016). The number of peer-reviewed papers per year and the maximum spatial coverage using RS techniques have been increasing over time. Most of the previous studies focused on vegetation monitoring.

As a general publication trend over time, we found that the number of papers, as well as the spatial extent of interest, have increased over the years; most papers were related to vegetation monitoring (Figure 1). In addition, we summarise and describe the reviewed publications in the following subsections based on five key findings:

1. Various DL algorithms with various RS data sources have been used for a few common problems.
2. The small data problem is a scale-dependent issue.
3. Data augmentation and transfer learning are popular, but other techniques are rarely used.
4. Reported model performances are suspiciously high, indicating a lack of appropriate evaluation schemes.
5. Using a small dataset has several attractive benefits.

3.1. Various DL algorithms using different RS data sources are used for a few common problems

RS and DL have had a major impact in many areas, particularly in vegetation-related applications (49
of the 80 articles), followed by land use / land cover classification (16 articles), and vehicle detection or classification (5 articles). The majority of the studies conducted classification (44 articles), followed by segmentation (19 articles), and object detection (17 articles). The majority (86%) of the studies had 1,000 or fewer annotated samples per class (median: 242 samples per class; mean 616). Few studies addressed a regression problem, but this does not necessarily indicate a lack of research on RS and DL for regression. Rather, it suggests that such tasks are more complex and require larger labelled datasets, as evidenced by the reliance on larger amounts of labelled data in several published studies (Osco et al., 2021; Yuan et al., 2020).

Vegetation-related applications included mapping crop type (Lange et al., 2022; Li and Stein, 2020; Odebiri et al., 2022), as well as monitoring plant health (Astolfi et al., 2021; F. Feng et al., 2022; Ho et al., 2022; Safonova et al., 2019; Zhixiang Xue et al., 2022) and predicting crop yields (Kim et al., 2021; H. Li et al., 2022; Pang et al., 2020; Sagan et al., 2021). For instance, around 800 labelled data points were used for classification of crops using Sentinel-1 data (Zhao et al., 2019), and around 300 field data points were used for yield estimation with Planet and WorldView data from 2D and 3D CNN (Sagan et al., 2021). In addition, RS has contributed to biodiversity conservation by its use in analysing complex ecosystems, tracking habitat changes, and identifying plant species. For example, Muro et al. (2022) used Sentinel-1 and -2 data in a DL model to predict plant biomass and species richness, using around 500 observations. Another example is a study by (Lange et al., 2022), where CNNs were used to map grassland use intensity.

Besides vegetation studies employing global satellite data, various other RS sources have been used. For example, one study focused on mapping urban areas used in high-resolution satellite imagery to create detailed maps of buildings and infrastructure (Li and Stein, 2020), while another study focused on monitoring changes in vegetation cover used in lower-resolution imagery from a different satellite sensor (Lioutas, 2020). In addition, a study of land cover mapping used a combination of different data sources, including aerial imagery, LiDAR, and field data (Sanlang et al., 2021; Uhl et al., 2021). Hyperspectral RS, a technology that acquires high-dimensional spectral information across hundreds of contiguous spectral bands, is another popular data source. However, obtaining manual annotations for hyperspectral data is challenging, leading to an insufficient number of labelled pixels (Chen et al., 2015; Pan et al., 2016). While DL techniques may hold potential for hyperspectral image classification (e.g., Spectral MugNet), further research is required to explore their effectiveness in scenarios with limited data (Jia et al., 2021a; Pan et al., 2018).

We also found that several studies used the same dataset repeatedly by using different DL algorithms. One series of studies (Blekos et al., 2020; Ding et al., 2022; F. Feng et al., 2022; H. Gao et al., 2021; K. Gao et al., 2021; Kang et al., 2019; Z. Wang et al., 2020; C. Wu et al., 2019; Xu et al., 2022; Zhixiang Xue et al., 2022; Zuo et al., 2020) used the same hyperspectral images (HSIs) from a dataset held by the Italian University of Pavia. Some of these authors compared these HSIs with other available HSI datasets: Salinas
six papers (Ding et al., 2022; K. Gao et al., 2021; Z. Wang et al., 2020; C. Wu et al., 2019; Zhixiang Xue et al., 2022; Zuo et al., 2020), Indian Pines – six papers (Ding et al., 2022; F. Feng et al., 2022; Kang et al., 2019; Z. Wang et al., 2020; C. Wu et al., 2019; Xu et al., 2022), Kennedy Space Center – two papers (H. Gao et al., 2021; Xu et al., 2022), and Houston – two papers (F. Feng et al., 2022; Zhixiang Xue et al., 2022).

Analysing the same dataset using different approaches is a reasonable way to confirm how well a new technique may perform in comparison to previous ones, but this repetition also indicates that similar investigations of various issues is still challenging, probably due to the small data problem. Nevertheless, we found that a few studies have investigated the monitoring of extreme events, including natural fire occurrences (Kato et al., 2021; Zhenyang Xue et al., 2022) and algal bloom events (Shin et al., 2022). We expect future studies to address other equally important global change events, such as conflicts, energy issues, and biodiversity problems.

3.2. The small data problem is a scale-dependent issue

The importance of spatial resolution and spatial extent in RS data is another factor that directly influences the level of detail captured and the subsequent insights that can be derived from the imagery (Kattenborn et al., 2019; Leitão et al., 2018). The small data problem becomes more pronounced when analysing high-resolution data, such as data obtained from Unmanned Aerial Vehicles (UAVs), which can offer centimetre-level granularity. This is because the fine-scale details captured in high-resolution imagery increase the variability and heterogeneity of the landscape, making it more difficult to generalise from a limited set of labelled examples. In contrast, satellite data with spatial resolution generally in the range of a few metres have different challenges related to labelled data. This relative lack of resolution can reduce the variability of the terrain and oversimplify the representation of features in the imagery.

Different sources of data also exhibit different advantages and disadvantages related to their spatial extent. Satellite data typically covers a much larger area compared to UAV data. The spatial predictions generated from satellite data can be reliable across vast regions if there is an adequate number of labelled samples and if their spatial distribution is representative of the entire area of interest (e.g., geographically isolated areas). The distribution of labelled data plays a critical role in the performance and generalisation capabilities of DL models trained on RS data. In contrast, when working with high-resolution UAV data, the focus is more on capturing the fine-scale details and variations within a smaller area of interest. In this context, the challenge lies in accurate local measurements that reveal subtle differences.

3.3. Data augmentation and transfer learning are popular, while other techniques are rarely used

Data augmentation and transfer learning (TL) have become very common ways to improve models
when applying DL techniques to RS data under conditions of small data. Our review found that 71% of all studies employed some sort of data augmentation technique (Shorten and Khoshgoftaar, 2019) while TL was present in 14 works (e.g., Guirado et al., 2017; Reedha et al., 2022; Yu et al., 2022). Data augmentation is a technique to artificially expand a dataset by creating new samples through various transformations, such as rotation, scaling, and flipping, to improve a model’s generalisability and robustness. Transfer learning is a technique where a pre-trained model, often on a large-scale dataset, is fine-tuned for a different but related task or dataset, leveraging the previously learned features to improve generalisability.

Various data augmentation techniques were used in most of the papers included in this review. The choice of data augmentation technique depends on the quantity, quality, and type of RS data. Most commonly, this method was applied to limited data from satellite imagery obtained from Landsat, WorldView, extremely high-resolution imagery, images from UAVs, and others. The most common methods of increasing RS data were: manual or automatic cropping of a large image or orthophoto image into small patches ranging from 15 × 15 pixels to 250 × 250 pixels or more, geometric image transformations (resizing, cropping, rotation, horizontal reflection, etc.), and colour transformations (changing contrast, brightness, colour, applying various noise filters, etc.). Nevertheless, as we show in the practical recommendation section, other DL techniques exist, but they are still rarely used.

3.4. Reported model performances are suspiciously high

While it was challenging to compare the studies under review in terms of model performance because they reported different metrics, we found an interesting but potentially problematic trend throughout the previous works. In essence, many studies tended to report an overoptimistic, overfit result, without testing model generalisability and transferability.

One of the most popular metrics was Accuracy (59 papers). The following evaluation metrics were also frequently used: Precision (P) in 39 papers, Recall (R) in 30 papers, F1 score (F1) in 28 papers, Kappa coefficient (k) in 16 papers, Intersection over Union (IoU) in 13 papers, mean Average Precision (mAP) in 10 papers, Sensitivity (S) in 3 papers, p-value by Freeman et al. (Freeman et al., 2019), Root Mean Squared Error by Wang et al. (D. Wang et al., 2022) and Hong-Yu et al. (Hong-Yu et al., 2023), Mean Absolute Percentage Error by (Barbosa et al., 2021), and Dice Similarity Coefficient by (Khan et al., 2021). Most papers used metric combinations (55 articles, 68%).

We found that the reported performance was extremely high. In 32 of the 59 articles reporting “Accuracy”, the score was 95% or more. Accuracy of 99-100% was achieved in 11 studies. Measurements of “Precision” were higher than 0.98 in some studies. The F1 metric was 90 or higher in at least 14 of the 28 papers. Some studies reported even 100% accuracy or an F1 metric of 100, which is a clear sign of overfitting. The tendency of these outstandingly high scores might result from the model evaluation scheme.
Typically, the test dataset should be collected independently from the data collection used for model training and validation, and the model performance should be evaluated using the test dataset. Otherwise, the model test was done for the same, biased dataset, e.g., the test was not done in another region, spatial autocorrelation was ignored, or the test was not done with data from other years. As a result, the models are neither generalisable nor scalable, but highly specialised for the particular data acquisition pipeline. Also, it is possible that augmented data was used in both training and test datasets. In the practical recommendation section, we suggest some promising solutions – cross validation in particular – to these problems.

4. **Using a small dataset has several attractive benefits**

It is often the case that it is impossible to obtain additional annotated data regardless of whether the researcher wants it or not: these include, for instance, studies that investigate rarely observed phenomena (e.g., climate extremes, rare species, and disease outbreaks), cover a specific narrow geographic space (e.g., a single agricultural field), are limited by time and resources (e.g., studies in low-income countries), or those that employ data recorded before digitalisation. However, this does not mean there are no advantages of using a small dataset to solve various RS problems by using DL.

One of the biggest advantages of using a small RS dataset is faster training times. This can be particularly useful for prototyping and experimentation with different models and hyperparameters. With smaller datasets, multiple models can be trained in a relatively short time, making it easier to compare and select the best model (Althnian et al., 2021; Prusa et al., 2015). Another benefit is reduced memory requirements and less storage. The use of a smaller dataset reduces the memory requirements, making it possible to train on resource-constrained devices, such as laptops or embedded systems (Katsaragakis et al., 2020). A small dataset may also make it difficult to train (overly) complex models with many parameters. In these cases, simpler models may indeed be more suitable; they also have the advantage of being easier to train and validate the performance of the model (D’Souza et al., 2020; Elsken et al., 2017; Keshari et al., 2018; Liu and Deng, 2015). The use of a small dataset combined with a low-complexity model can still result in sufficient performance (Brigato and Iocchi, 2020). Collecting and labelling an RS dataset is in some cases a complex, time-consuming, and costly task for research centres and organisations, which often leads to the use and preparation of a small set of available data. It could be drone data, digital camera imagery, or a few plots of satellite data. Thus, the use of a small dataset can reduce operating costs (Wang et al., 2023; Zhao, 2017). Finally, small datasets are easier to annotate, which is useful in cases where manual annotation is required.

Of course, small datasets have downsides as well. The main disadvantage is the lack of generalisability and transferability due to overfitting (B. Liu et al., 2017), resulting in poor performance.
when using unforeseen datasets (Bailly et al., 2022; Power et al., 2022; X. Wu et al., 2021). Small datasets also may be biased (Althnian et al., 2021; Lones, 2023; Schat et al., 2020).

5. **Practical recommendations for DL implementation strategies**

In the previous section, we noted that data augmentation and transfer learning are popular, but other techniques are rarely used. To address this issue, this section offers practical recommendations on strategies for the implementation of DL. We introduce the following techniques: TL, self-supervised learning, semi-supervised learning, few-shot learning, zero-shot learning, weakly supervised learning, process-aware learning, multitask learning, and ensemble learning. The literature search in this section was conducted in the same way as the previous search for major issues. However, we added a query that was able to return studies applying one of the above-mentioned techniques (e.g., “transfer learning”, “semi-supervised learning”, “few-shot learning”) to the main search keywords. We found 32 articles as of 16 February 2023 (Figure 2). We also present a practical flowchart for deciding which algorithm to use in each specific use case (Figure 3). We do not explicitly cover other methods such as data augmentation and regularisation, since they have been widely covered in various literature, such as by the work by Shorten and Khoshgoftaar (2019).

![Figure 2. The number of articles that use particular DL techniques addressing the small data problem in RS applications as of February 2023.](image-url)
Figure 3. Practical flowchart for selecting an appropriate deep learning technique (as of May 2023) to address the small data problem in remote sensing applications.

5.1. Transfer learning

As described before, TL is a popular technique that derives learning from one task and reuses it to solve another (similar) task. As (Iman et al., 2022) have explained TL is widely used in labelled dataset fields such as radar images, medical images, malware classification, facial emotion recognition, mechanics, vision, human activity recognition, civil engineering, Natural Language Processing (NLP), military, human sciences/psychology, chemistry, security, physics/astrophysics, and telecommunications.

Typically, TL takes place when a neural network is pre-trained on a large dataset, such as ImageNet (Russakovsky et al., 2015), and then its weights are used to fine-tune it on a smaller dataset for a specific task. TL can also be used as a feature extraction method to develop a second model that can be trained on the target data. The idea of TL is to apply knowledge from the source task to the target task, potentially improving performance, reducing the need for large training data, preventing overfitting, reducing the otherwise huge computation cost, and saving time (Rawat and Wang, 2017). Pre-training on a general dataset is particularly effective when the task-specific dataset is small or when there is limited labelled data available.

We found three ways that TL was used in the literature: fine-tuning a pre-trained model, using pre-trained features as input for a new model, and combining pre-trained models. Fine-tuning involves taking a pre-trained model and training it further on the target task (Dong et al., 2021; Ziegler et al., 2020). Using pre-trained features means that the output of one or more layers of a previously trained model is used to develop a new model trained on the target task. Combining pre-trained models involves training multiple pre-trained models on related tasks and then subsequently combining them to make predictions about a different, previously unexplored phenomenon.

TL is already actively used to solve a variety of problems in RS when the dataset is small. We found
a total of 14 papers regarding the use of TL in RS on a small sample. For example, a paper by (S. Wang et al., 2018) proposed a DL framework for RS image registration based on TL that would reduce the huge computational cost in the training stage, speed up the framework, and achieve additional performance gains. The experiments conducted on seven sets of RS images acquired by RADARSAT, SPOT, and Landsat showed that the proposal improved registration accuracy by between 2.4% and 53.7%.

H. Zhang et al. (2019) used TL to classify HSI due to very limited training data and the massive parameters of end-to-end 3-D lightweight models. Moving to the problem of radar-jamming detection Hou et al. (2022) and Lv et al. (2022) separately proposed methods based on TL. In (Character et al., 2021), researchers used TL not only to compensate for a small dataset (Lidar and Sonar), but also to address false positives by training the YOLOv3 model on both shipwrecks and background topography. Another example was forest-fire detection using YOLOv5 by Zhenyang Xue et al. (2022), improving the performance of mAP@0.5 by up to 10.1%. S. Wang et al., (2022) applied TL to weed density extraction based on few-shot learning through UAV and multispectral images in an ecological irrigation area using a pre-trained AlexNet algorithm.

A kind of TL known as domain adaptation was applied to synthesise training data under diverse environmental conditions with automatic labels using YOLOv3 (W. Zhao et al., 2021). The results from that paper showed that their proposed method improved bale detection. Moreover, this approach could be easily scaled to many other crop field objects. J. Chen et al. (2022) used the Faster R-CNN domain adaptation for aircraft detection on the DOTA dataset. In (Yu et al., 2022), the authors showed that their method based on TL could accurately extract terraced field surfaces and segment terraced field boundaries with an overall accuracy above 93.12%.

In another experiment, TL solved the problem of poor adaptability of the DenseNet-121 network to RS images acquired from different platforms, and was able to properly identify disaster-damaged buildings (Yang et al., 2021). Other examples included scattering shrub detection (Guirado et al., 2017), fir tree detection (Safonova et al., 2019), HSI classification (F. Feng et al., 2022), land cover classification (Naushad et al., 2021; Qiu et al., 2022), and seismic data analysis (El Zini et al., 2020). The average accuracy in these works after applying TL to the new small datasets was over 93%.

Key recommendations for using TL include selecting the right pre-trained model, determining the level of TL (feature extraction, fine tuning, or both), determining which layer(s) to transfer, generously employing data augmentation, regularising the network, and evaluating performance. One common practice is to import and use ready-made models from DL libraries such as TensorFlow, Keras, Theano, and PyTorch. The most popular models were AlexNet, VGG, Xception, Inception, MobileNet, DenseNet, ResNet, GoogleLeNet, and YOLOs. In (Abu et al., 2022; Sharma et al., 2021; Zhao, 2017), all suggested considering fine-tuning several hyperparameters (feature map, filter size, activation function, pool size, optimiser, learning rate, batch size, epoch, dropout rate, loss function, and evaluation metric) of the pre-
trained model.

5.2. Self-supervised learning

Self-supervised learning is a technique related to transfer learning. However, in contrast to traditional transfer learning, self-supervised learning does not require labelled data for pre-training – it can leverage the structure of unlabelled data to generate labels for the pre-training task. However, like transfer learning, a model pre-trained with self-supervised learning is further fine-tuned on the labelled downstream task (Rani et al., 2023).

This technique has been employed in medicine and healthcare (Chen et al., 2019; Krishnan et al., 2022), physics (Ma and Liu, 2020), speech representation (Mohamed et al., 2022), RS (S. Wang et al., 2022), time-series analysis (Pöppelbaum et al., 2022), video processing (Jing and Tian, 2019; Z. Wang et al., 2022; Yan et al., 2020), speech processing (Hsu et al., 2021), and target tracking (Yuan et al., 2021) for example. The most-cited papers involve medical research, solving problems such as accurate detection of tissue in monocular endoscopy (X. Liu et al., 2019), retinal disease diagnosis (X. Li et al., 2020), MRI parameter mapping or reconstruction (Liu et al., 2021; Yaman et al., 2020), 3D medical-image analysis (Zhu et al., 2020), and homography estimation (Wang et al., 2019).

However, we only found four papers dealing with self-supervised learning in RS using a small sample (Bing Liu et al., 2022; Rangnekar et al., 2020; Song et al., 2022; Zhixiang Xue et al., 2022). These were related to solving the HSI classification problem. The main reason for using self-supervised learning was the scarcity and high cost of labelled HSI samples. In (Song et al., 2022), the authors proposed a dual-branch residual neural network (ResNet) to fuse spectral and spatial information. Zhixiang Xue et al. (2022) proposed a generative self-supervised feature learning architecture for multimodal RS-imaged land cover classification. In this case, the self-supervised feature learning architecture was able to extract highly sophisticated, robust feature representations from multi-view data; this process did not require any labelled information, thus alleviating the otherwise critical need for annotated samples. To solve the same problem, (Bing Liu et al., 2022) presented a novel ensemble self-supervised feature learning method using multiple HSI datasets. Rangnekar et al. (2020) compared the performance of SegNet, U-Net, and Res-U-Net for scene understanding and object identification by using dense semantic segmentation to establish a benchmark for a given scene.

Despite the fact that the use of self-supervised learning technology on small datasets is relatively unexplored, we have come across some works on similar topics (Cao and Wu, 2021; Su et al., 2020). Su et al. (2020) presented a systematic study by varying the degree of domain shift and analysing the performance of multiple meta-learners on a variety of domains. The authors found that the improvements were greater when the training set was smaller or the task was more challenging. They also noted that self-supervised
learning can degrade performance if the distributions of the images used for meta-learning and self-supervised learning are different. Cao and Wu (2021) proposed a system of scaled-down self-supervised learning, which included three parts: small resolution, small architecture, and small data. The authors showed that this approach could achieve impressive results on small data alone, even without a large pre-training dataset.

5.3. **Semi-supervised learning**

Semi-supervised learning is a technique that has been actively implemented in a number of different areas over the past few years. Self-supervised learning is a mix of supervised learning and unsupervised learning to leverage unlabelled data, in which a model is repeatedly trained and updated using both the labelled and the generated pseudo-labels (that is, predicted labels) for the unlabelled data. This can result in better performance than supervised learning alone (Han et al., 2022; L. Wang et al., 2021).

Across all scientific disciplines, one of the most-cited papers was presented by (W. Ma et al., 2019) dealing with probabilistic representation and the inverse design of metamaterials. Another work was dedicated to detecting fake users on Twitter (BalaAnand et al., 2019). Later, Xu et al. (2021) presented a paper on image recognition and facial attribute recognition using a semi-supervised, self-growing generative adversarial network (SGGAN). The authors claimed that when they used training data with only 4% labelled facial features, their approach was nevertheless able to achieve accuracy comparable to that of leading supervised DL methods with all labelled facial features. Rostami et al. (2020) used semi-supervised learning to choose a subset of available features that had the lowest redundancy with each other but also the highest relevancy to the target class with limited training data in a Synthetic Aperture Radar (SAR) classification. Tseng et al. (2021) proposed DNetUnet for medical image segmentation. As of 2022, some of the most cited papers investigated road damage detection (Shim et al., 2022), drift compensation for olfactory sensors (Lu et al., 2022), and mechanical fault diagnosis (Y. Feng et al., 2022).

As for the implementation of the semi-supervised learning strategy in the field of RS under conditions of small sample sizes, we came across only two articles. Jozdani et al. (2021) deployed a teacher-student semi-supervised learning approach (based on the U-Net and U-Net++ networks) involving unlabelled UAV and WorldView-2 data to assist with improving model performance to map caribou lichen. This approach produced a reasonably accurate (overall accuracy of 85% and F1 score of 84%) lichen map at the WorldView scale.

Although semi-supervised learning is suitable for unlabelled data, it is recommended to use labelled data because the quality of the labelled dataset will directly affect model performance. Another important point is to experiment with different ratios of labelled and unlabelled data to find the optimal balance for a particular task (Chapelle et al., 2009; He et al., 2021).
5.4. Few-shot learning

The goal of few-shot learning is to teach models to generalise for new tasks or problems with only a few labelled examples per class. Few-shot learning is therefore a type of meta-learning, which involves training a model on a set of related tasks so that the model can then learn to quickly adapt to new, similar tasks with only a few examples (Hospedales et al., 2020). This method has gained popularity in RS for its ability to solve the problems of agriculture and areal scene classification (Li and Yang, 2021; Zhang et al., 2021). Recently, (K. Gao et al., 2021), (Zuo et al., 2022), and (Z. Li et al., 2022) all applied meta-learning to HSI classification. Another approach is to use a widely cited generative adversarial network to teach the model a high-level representation of the data (Goodfellow et al., 2014). Despite the widespread popularity of such methods in the field of medicine (Yi et al., 2019), they are only recently beginning to be used in RS (Liu et al., 2018; Zhong et al., 2020; Zhu et al., 2018).

The application of few-shot learning in RS was found in seven articles in our search: (J. Bai et al., 2022), (Z. Li et al., 2022), (J. Liu et al., 2022), (Rao et al., 2019), (Zuo et al., 2022), (S. Wang et al., 2022), and (T. Wang et al., 2022), and other. Most of the papers dealt with HSI classification problems. S. Wang et al. (2022) proposed weed and crop density extraction using RGB and multispectral images in an ecological irrigation area. B. Liu et al. (2019) proposed an algorithm based on few-shot learning in three steps. First, spectral-spatial features are extracted to reduce the labelling uncertainty via a deep residual 3-D CNN. Second, the network is trained in episodes to learn about a metric space where samples from the same class are close and those from different classes are far. Finally, the testing samples are classified by a nearest neighbour classifier in the learned metric space. A similar algorithm was also proposed by J. Bai et al. (2022). A small-scale high-precision network called “3-D convolution random Fourier features (3-DCRFF)” was presented by T. Wang et al. (2022). Yet another method was based on an edge-labelling graph neural network (FSL-EGNN) created by Zuo et al. (2022).

5.5. Zero-shot learning

Zero-shot learning is a special type of few-shot learning method, which is trained to recognise objects or classes it has never seen before. The model is trained on a set of known classes or objects, but is also given additional information about the relationships between these classes, such as semantic or visual similarities (Y. Wang et al., 2020). This additional information is used to help the model recognise new, unseen classes or objects that are related to the known classes. This method is useful in situations where it is difficult or expensive to obtain labelled data for new classes or objects. The method has been applied to medical image segmentation (G. Wang et al., 2018), attribute-based classification (Lampert et al., 2014), industrial fault diagnosis (Y. Feng et al., 2022), and label-embedding for image classification (Akata et al.,
We found only one article in RS applications, by Sumbul et al. (2019). Their paper presented object recognition for 40 different types of street trees using areal data. Experiments showed that their proposed model achieved a 14.3% normalized recognition accuracy for the classes with no training examples, which was significantly better than a random guess accuracy of 6.3% for 16 test classes, as well as the accuracy levels of three other zero-shot learning algorithms.

Both few-shot and zero-shot learning methods can be a valuable technique for extracting the best performance from limited data (Villon et al., 2021; H. Zhang et al., 2019). However, when using them with small samples, special attention should be paid to data augmentation, the selection of an appropriate evaluation metric, and the ensemble of multiple few-shot learning models. All of these can significantly improve the performance of the model.

5.6. Active learning

Active learning is a powerful technique that can help ML models achieve greater accuracy, while reducing the amount of labelled data required (Ren et al., 2021; Settles, 2009). This technique involves selecting the most informative examples, labelling them, and adding them to the training dataset. Active learning has been successfully applied in many disciplines, including NLP (Arora and Agarwal, 2007; Zhang et al., 2022) and computer vision (Takezoe et al., 2022; M. Wu et al., 2022). The idea of active learning use in RS in particular has been presented by P. Liu et al. (2017) and Cao et al. (2020) for HSI image classification. Some of the benefits of active learning include reduced labelling costs, faster training, and improved accuracy compared to randomly selecting examples for labelling. Active learning can be especially useful for small datasets, as it allows the model to learn more efficiently from a limited number of labelled examples. However, due to this data limitation, the model may be more prone to overfitting. To avoid this, we recommend applying regularisation methods and monitoring the performance of the model during training.

5.7. Weakly supervised learning

In cases when collecting full ground-truth labels is time-consuming, expensive, or otherwise practically impossible, then it is useful to use weakly supervised learning (Zhou, 2018). This is a type of ML in which the training data has been labelled partially, noisily, or imprecisely. One popular application of this is label propagation: the use of a small set of labelled data to generate labels for a larger set of unlabelled data. Another application is multi-instance learning, where each point of the training data exists in multiple instances, but a subset of these instances are labelled.

Weakly supervised learning has been successfully applied in various applications, including image classification, object detection, semantic segmentation, and NLP. However, the use of weakly supervised
Weakly supervised learning has the potential to reduce the cost and effort of collecting labelled data, and can be used in various applications where obtaining fully labelled data is difficult or impractical, even in small datasets. One common approach is to use transfer learning and active learning, which can help improve model performance. In addition, using the weakly supervised learning method with limited data can help reduce the need for large amounts of labelled data, while still achieving high accuracy.

5.8. Multi-task learning

Multi-task learning is another powerful technique that can be implemented in RS when only a small dataset is available. It is designed to improve the performance of multiple related learning tasks by leveraging useful information among them (Zhang and Yang, 2018). The goal is to develop a model that can learn to generalise well about new instances of each task, while also benefiting from the shared knowledge learned across all tasks. This means that the model learns to solve multiple related problems using the same or shared representations, instead of developing independent models for each task. The model typically shares lower-level layers across all tasks, while having task-specific layers at higher levels. This way, the model can extract general key features shared across multiple tasks.

Multi-task learning’s impressive track record has helped it gain popularity in recent years. The frequency of publications describing the use of this technology is growing by 25-30% every year. It has led to success in many ML applications, from NLP and speech recognition to computer vision and drug discovery (Ruder, 2017; Sosnin et al., 2019; Zhao et al., 2023). Multi-task learning is also actively used in RS, particularly for classification (Qi et al., 2017), target detection (X. Wu et al., 2019; Zhang et al., 2017),
semantic segmentation (Y. Li et al., 2022; Volpi and Tuia, 2018), and feature representation tasks (Xiong et al., 2019). However, its application when using a small number of training samples is still rare, as only a single paper by Zhao et al. has discussed this (P. Zhao et al., 2021). Their paper proposed a multi-aspect SAR target recognition method based on a prototypical network. This method can significantly improve the recognition performance of the DL model under a small number of samples, and thus the recognition accuracy can approach that of a model with a complete training set.

5.9. **Ensemble deep learning**

Ensemble learning is a method that combines many individual models to obtain better generalisation performance (e.g., random forests and boosting). While this approach is commonly used for tabular data analysis, its application in DL models is far less popular because it requires huge computational resources and time. Nevertheless, ensemble DL models have the potential to harness the benefits of DL architecture as well as ensemble learning (e.g., to avoid overfitting). Previously, this method has been applied to predicting short-term traffic flow (Zhang and Xin, 2022), predicting plant miRNA–IncRNA (Hamdy et al., 2023), and identifying the drivers of vehicles by using Controller Area Network (CAN) bus data (Hu et al., n.d.). Ganaie et al. also reviewed a variety of techniques that have been applied in different domains (Ganaie et al., 2022). Bing Liu et al. (2022) presented a novel ensemble self-supervised feature learning method on multiple HSI datasets. Since any of the above-mentioned learning techniques can be combined, ensemble learning has promising potential for further applications.

5.10. **Process-aware learning**

Process-aware learning refers to the process of incorporating knowledge into ML models about the underlying processes or mechanisms that generate data. It is particularly helpful for understanding the underlying causal relationships between variables, thus leading to better predictions and decisions. One popular application is known as “physics-informed learning” (Karniadakis et al., 2021) in the domain of physics. Although we did not find the process-aware learning approach in any RS domain, we can imagine several use cases. For instance, researchers could use a vegetation growth model to simulate parameters that are difficult to measure in the field, use these simulated parameters as labelling for images, and then train a DL model with the labelled data.

5.11. **Practical recommendations for DL model selection and validation strategies**

As we mentioned above, it seems that previously reported model performances have been suspiciously high, indicating a lack of appropriate evaluation systems. Applying an appropriate validation strategy is important for model generalisability and transferability (Vabalas et al., 2019), while preventing
overfitting (Ying, 2019).

The most commonly used type of validation strategy in ML is cross-validation (Little et al., 2017). This procedure is quite common in ML via tabular dataset analysis, but it is rarely applied to large datasets for DL. We believe that k-fold cross-validation would be useful for evaluating DL model performance with a small dataset – and this capacity for validation is another benefit of using a small dataset. Moreover, in the area of RS, random sampling for validation may not be the best idea, because spatial and temporal data typically reveal high autocorrelation levels. Several recent studies have pointed out that autocorrelation leads to a violation of the assumption of data independence between training data and the validation set (Kattenborn et al., 2022; Le Rest et al., 2014; Ploton et al., 2020). Spatial rather than random cross-validation can be used for less biased model assessments (Roberts et al., 2017).

The cross-validation technique was used by Xue et al. (2019) and by Chen et al. (2018) to solve problems with estimating PM2.5 concentrations across China, and (Yang et al., 2018) to estimate grassland biomass. Other case studies have included mapping soil properties from high-resolution RS data (Forkuor et al., 2017), mapping fire intensity (Gibson et al., 2020), and quantifying rangelands (Rigge et al., 2020). We found four papers that directly investigated cross-validation for RS imagery under small sample conditions (Freeman et al., 2019; Lange et al., 2022; Odebiri et al., 2022; Z. Wu et al., 2021). All the publications applied random cross-validation with different fold sizes (4 and 10 folds), each at different scales (local, regional, and national). The tasks performed were the mapping of regressed soil organic carbon content, HSI-based land cover classification, and plant water stress detection.

6. Conclusions

In this review paper, we performed a survey of the small data problem in RS data in DL implementation and suggested promising DL techniques to address the problem. First, we summarised 80 studies from 2016 to 2023, and presented the possibilities to address the small data problem with advanced DL techniques beyond conventional learning methods. For this, we first had to define what “small data” means. Then, we described the few previous studies that had analysed RS processes employing DL techniques under conditions of small data, and we looked at the advantages and disadvantages of using small datasets. Finally, we offered a set of practical recommendations about how RS scientists can better implement DL techniques to fully take advantage of a small dataset. As one previous paper noted (Keshari et al., 2020) a variety of approaches can be used to solve the small data problem, such as data augmentation, data fine-tuning, the adaptation of pre-trained models, and reducing the dependence on large-sample learning. However, in our review, we also presented even more techniques that are worth considering when working with a small dataset. We identified a total of ten learning techniques for addressing the small data problem: Transfer learning, self-supervised learning, semi-supervised learning, few-shot/zero-shot
learning, active learning, weakly supervised learning, multitask learning, ensemble learning, and process-aware learning. Cross-validation is also a valuable tool for improving the use of DL in RS (Figure 3). Our goal has been to show ways to implement DL applications for research where ground-truth (annotation) data is difficult to obtain, while making it possible to solve various problems involving classification, detection, or segmentation. These problems could include biodiversity loss, climate extremes, and sudden changes in socio-environmental systems. For future work, we plan to apply different DL strategies to solve various practical problems in RS under small dataset conditions, where this modern technique has not been adequately used. Finally, we hope that by justifying the use of small datasets, this review will motivate more researchers to experiment with other techniques and apply them to different RS problems.

**Abbreviations**

The following abbreviations or terms are used in this review paper:

- **RS** Remote Sensing
- **AI** Artificial Intelligence
- **ML** Machine Learning
- **DL** Deep Learning
- **CNN** Convolutional Neural Network
- **TL** Transfer Learning
- **NLP** Natural Language Processing
- **HSI** Hyperspectral Imaging
- **UAV** Unmanned Aerial Vehicle

**Declaration of Competing Interest**

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

**Acknowledgments**

This study was supported by the Federal Ministry of Education and Research (BMBF – Bundesministerium für Bildung und Forschung) project “Multi-modale Datenintegration, domänenspezifische Methoden und KI zur Stärkung der Datenkompetenz in der Agrarforschung” (16DKWN089). **Explanation:**

- **Zhou et al. (2022)**: Recognition
  - 10 classes: MSTAR dataset of vehicles as 2S1, D7, T62, BRDM, ZIL131, ZSU234, BMP2, BTR70, BTR60, T72
  - Same size of 200 × 200 pixels
  - The MSTAR public dataset collected by the X-band SAR automatic target recognition (SAR-ATR) sensor, 2,425 images

- **Han et al. (2020)**: Classification
  - 3 classes: white ice, grey ice, and seawater
  - 4 classes: white ice, grey white ice, grey ice, and seawater
  - 3 classes: white ice, grey ice, and seawater
  - 3 datasets of HSI: Baffin Bay image captured by Earth Observing-1 (EO-1) satellite, 176 bands; Bohai Bay image captured by EO-1 satellite, 1,247 samples; Liaodong Bay image captured by Landsat-8 satellite, 1 image

- **Chew et al. (2020)**: Detection
  - 6 classes: banana, maize, legume, forest, structure and other

- **Liu et al. (2020)**: Classification
  - 13 classes: impervious surfaces, buildings, low vegetation, trees, cars, clutter/background, farmland, forestland, bare soil, building area, water, road, artificial structures
  - 2 datasets: ISPRS 2D semantic labelling contest of Vaihingen, 33 images; Shanghai dataset, 6 images

- **Tian et al. (2020)**: Classification
  - 11 classes: forest species as M. Laosensis, P.elliottii, P. massoniana, E. urophylla, E. grandis, C. hystrix, A. Meloxylon, M. laosensis, soft broadleaf, cutting site, and road
  - HSI dataset was housed in a LiCHy system that integrates light detection and ranging (LiDAR), a charge-coupled device camera, an AISA Eagle II hyperspectral sensor, and an inertial measurement unit (IMU), 125 bands

- **He et al. (2020)**: Detection
  - Wheat plant

- **J. Chen et al. (2022)**: Detection
  - Aircraft

- **Su et al. (2021)**: Semantic segmentation
  - 2 classes: crops and weeds
  - 2 datasets: Narrabri and Bonn from the wheat farm (4-channel RGB + NIR camera JAI AD-130 GE), 283 and 150 images

- **Kato et al. (2021)**: Classification
  - 8 classes: volcano, factory, oil platform, fire (grass), fire (forest), fire (urban), specular reflection, non-typeable
  - Landsat OLI (11 bands) and Thermal Infrared Sensor (TIRS) and Sentinel-2 MSI (12 bands), 2,516 images

- **Rusin et al. (2021)**: Segmentation
  - 6 classes: mixed forest, field, city, forest belt, ordered forest, water
  - Dataset from WorldView-2 satellite 1.267 × 1,265, 64 parts

- **K. Gao et al.**:
  - 9 classes: University of Pavia dataset – asphalt, meadows, 3 HSI datasets:

3 HSI datasets: UP, ROSIS, 610 × 340 pixels with 103 bands; SA, AVIRIS, 512 × 217 pixels with 224 bands; Pavia Center (PC), 1,096 × 715 pixels with 102 bands

NWPU-RESISC45 dataset

Dataset from DJI-Phantom 4 Pro UAV, 400 images

Dataset of Landsat 8 from USGS and NASA with OLI/TIRS sensors, 7 bands, 2015–2019

Dataset from UAV DJI Phantom 3 Pro with an integrated Sony EXMOR 1/2.3” camera, 400 images

2 datasets from airborne synthetic aperture radar (AIRSAR) Flevoland data and GF-3 data, Polarimetric Synthetic Aperture Radar (PolSAR) images
16 classes: Indian Pines dataset – alfalfa, corn-no till, corn-min till, corn, grass-pasture, grass-trees, grass-pasture-mowed, hay-windrowed, oats, soybean-no till, soybean-min till, soybean-clean, wheat, woods, building-grass-trees-drives, and stone-steel-towers

9 classes: University of Pavia dataset – asphalt, meadows, gravel, trees, painted metal, sheets, bare soil, bitumen, self-blocking, bricks, and shadows

3 datasets: IP, SA, and UP

3 classes: poplar trees, coniferous trees, and background

Crop detection

16 classes: Indian Pines dataset – alfalfa, corn-no till, corn-min till, corn, grass-pasture, grass-trees, grass-pasture-mowed, hay-windrowed, oats, soybean-no till, soybean-min till, soybean-clean, wheat, woods, building-grass-trees-drives, and stone-steel-towers

9 classes: University of Pavia dataset – asphalt, meadows, gravel, trees, painted metal, sheets, bare soil, bitumen, self-blocking, bricks, and shadows

2 HSI datasets: IP and UP

Caribou lichen

2 classes: olive tree and its shadow

10 classes: forest, annual crop, highway, herbaceous vegetation, pasture, residential, river, industrial, permanent crop, and sea/lake

7 classes: coniferous tree (high density), field 1, field 2, mixed wood (high density), cluster mixed forest, mixed wood (medium density), and common larch

Image from GeoEye-1 satellite

Dataset from Zenmuse-X4S camera-equipped DJI-Inpire-2, 243 and 100 images

2 HSI datasets: IP and UP

Dataset from DJI Inspire-1 UAV and 8-band WorldView scene, 1,825 samples

Dataset from Parrot Disco-Pro AG UAV and DJI-Phantom 4 UAV, 600 images

MSI EuroSAT dataset from Sentinel-2 satellite, 13 spectral bands consisting of 27,000 labelled and georeferenced images, with 2,000–3,000 images per class

Image from WorldView-2
