Abstract

Understanding the physical properties of fault zones is essential for various subsurface applications, including carbon capture and geologic storage, geothermal energy, and seismic hazard assessment. Despite improvements in fault imaging and visualisation, predicting the physical properties of faults and fault zones in the subsurface remains challenging, even with high-quality seismic reflection data. In this study, we use borehole and high-quality Post-Stack Depth Migrated (PSDM) seismic reflection and Full-Waveform Inversion (FWI) velocity data to investigate the characteristics of fault zones in the Samson Dome in the SW Barents Sea. We analyse the variance attribute of the PSDM and FWI volumes, revealing linear features that consistently appear in both datasets. These features correspond to locations of rapid velocity changes and seismic trace distortions, which we interpret as faults. These observations demonstrate the capability of FWI in recovering fault zone velocity structures. Our findings also reveal the natural heterogeneity and complexity of fault zones, with varying P-wave velocity anomalies within the studied fault network. We propose that these anomalies may indicate differences in fault transmissibility. Our study highlights the potential of FWI velocity models in predicting fault zone physical properties and improving subsurface interpretations. By integrating seismic reflection data and FWI models, we can enhance our understanding of fault zone architecture, which has implications for energy transition policies, carbon storage, geothermal energy development, waste disposal, and seismic hazard mitigation.

Supplementary material: Additional seismic depth slices are available at https://doi.org/xxxx.

27 Faults play a major role in controlling subsurface fluid flow by juxtaposing impermeable lithologies against

28 permeable ones, or by containing fine-grained, low-permeability (i.e., sealing) fault rocks (e.g., Welbon et

29 al., 1997; Bailey et al., 2006). Determining the sealing potential of faults typically involves the integration

30 of seismic reflection and wellbore data (e.g., Manzocchi et al., 2010; Yielding et al., 2010). Historically,

31 understanding the variability in fault permeability played a major role in hydrocarbon exploration,

32 production and in determining compartmentalisation, and overall economic viability of hydrocarbon

33 reservoirs (e.g., Bailey et al., 2002; Jolley et al., 2010; Fisher et al., 2018). However, a better understanding

34 of the subsurface and more specifically the hydraulic properties of faults, is increasingly required to

35 comply with government-mandated regulations and to provide public assurances of several net-zero

36 solutions (e.g., Kaldi et al., 2013), whether this relates to carbon capture and geologic storage, producing

37 geothermal energy, designing radioactive waste disposal sites, locating water resources, or mitigating

38 seismic hazards (e.g., de Laguna et al., 1968; Morris et al., 2004; Chiaramonte et al., 2015; Morell et al.,

39 2018; Daniilidis et al., 2021; BGS, 2022).

40 Seismic reflection data have been widely used to reveal the presence, geometry, and evolution of

41 subsurface structures, including normal faults (e.g., Boyer & Elliott, 1982; Childs et al., 2003). Traditionally,

42 those studies involve seismic interpretation workflows to map discontinuities in seismic sections that

43 delineate offsets in stratal reflections (e.g., Wernicke, 1995). Although often expressed as discrete, planar

44 features, field data show that faults comprise zones of deformation (e.g., Kim et al., 2004; Childs et al.,

45 2009). Previous studies using seismic reflection data have demonstrated that normal faults are expressed

46 as seismic disturbance zones (*sensu* Iacopini et al., 2016). The extent of the related fault damage zone can

47 be visualised using seismic attributes, and it has been shown to be of comparable width to exposed

48 damage zones (e.g., Alaei & Torabi, 2017). The way a fault is expressed in seismic reflection data depends

49 on the frequency and quality of the seismic data, with faults appearing as planar features at low

50 frequencies and as zones or extractable bodies or volumes at higher frequencies (e.g., Botter et al., 2016).

51 It has been long recognised that mapping faults using seismic reflection data is a relatively

52 subjective exercise, especially in terms of defining fault geometries in map-view and the displacement

53 distribution across a faults surface (e.g., Freeman et al., 1990). This appreciation of subjectivity caused

54 several authors to focus more on finding robust and perhaps more objective interpretation methodologies

55 that utilise the full extent of the imaging power of seismic reflection data (e.g., Freeman et al., 1990;

56 Hesthammer et al., 2001; Braathen et al., 2009). For example, seismic attributes have been developed to

57 identify faults and permit more detailed analysis of their geometries (e.g., Jones & Knipe, 1996; Randen

58 et al., 2001; Chopra & Marfurt, 2005; Iacopini & Butler, 2011) and the style and magnitude of related (i.e.,

59 offset) strain (e.g., Freeman et al., 2008; Braathen et al., 2009; Iacopini et al., 2016). More recently,

60 machine learning and increased computational power have allowed the development of data-driven,

61 automated fault interpretation workflows (e.g., Meldahl et al., 2001; An et al., 2021; Wrona et al., 2021;

62 An et al., 2023). However, despite these improvements in fault imaging and visualisation, predicting the

63 physical properties of faults and fault zones (i.e., fault zone width, shale/clay smear content,

64 transmissibility, and fluid content) in the subsurface remains challenging, even with high-quality seismic

65 reflection data.

66   Full-waveform inversion (FWI) is an advanced method of seismic imaging that aims to recover

67 high-fidelity physical property models of the subsurface using the full recorded wavefield (i.e., both

68 reflection and refraction waves) from seismic surveys, as opposed to traditional velocity modelling

69 workflows based on first-arrivals (e.g., Virieux & Operto, 2009; Morgan et al., 2013; Warner et al., 2013

70 for more details). Theoretically, any physical properties of rock units that influence seismic waves (such

71 as P-wave, S-wave velocities, and density) can influence the recorded seismic wavefield and, therefore,

72 be revealed by FWI models (e.g., Warner et al., 2013; Tromp, 2020; Davy et al., 2021). However, in

73 practice, the majority of FWI studies, particularly in 3D, have focused on the recovery of P-wave velocity.

74 Some of these FWI studies in subduction zones and sedimentary basins have qualitatively demonstrated

75 the ability of FWI models to image fault zones characterised by varying velocities relative to their

76 surrounding host rocks (e.g., Morgan et al., 2013; Gray et al., 2019; Davy et al., 2021). We hypothesise

77 that this velocity variability is related to changes in fault zone hydraulic properties, as captured by

78 parameters such as Shale Gouge Ratio (SGR). As such, the FWI itself may be a potential 'screening' tool to

79 assess fault transmissibility within a fault network. In this study, we test this hypothesis by using high-

80 quality, depth-migrated 3D seismic reflection and FWI data from the Samson Dome, SW Barents Sea,

81 offshore Norway. We compare our recovered fault velocities with modern stress-field orientations and

82 the results of tradition shale-gauge ratio methods (the current state-of-the-art in determining fault

83 transmissibility; e.g., Bretan, 2023). Ultimately, we showcase initial attempts to improve our

84 understanding of the physical properties of fault zones by combining seismic reflection and FWI velocity

85 data.

86

Geological Setting

The Barents Sea is a shallow continental shelf that encapsulates an area of c. 1.3 million km2 offshore Norway between the Arctic Ocean to the north and the Russian and Norwegian coastlines to the south (e.g., Gabrielsen, 1984; Doré, 1995). The large-scale structures in the region were formed as a result of multiple phases of rifting from the Devonian to the opening of the Norwegian and Greenland seas and the onset of seafloor spreading in the Eocene (Faleide et al., 1984, 1993, 2008; Gabrielsen, 1984; Gabrielsen et al., 2016). Our study area is located over the Samson Dome, a structure thought to have formed due to salt movement during the Middle to Late Triassic (e.g., Breivik et al., 1994; Mattos et al., 2016). The stratigraphy in the Samson Dome is dominated by siliciclastic rocks, with minor carbonate intervals, particularly in the Lower Permian (e.g., Breivik et al., 1994). A detailed lithology report for wellbore 7224/7-1 can be found on the Norwegian Petroleum Directorate (NPD) webpage (https://factpages.npd.no/en/wellbore/PageView/Exploration/All/1245). A major unconformity likely formed in the Late Cretaceous to Paleogene, eroding part of the Upper Cretaceous capping the Samson Dome (e.g., Faleide et al., 2008). The sediments overlying the unconformity are associated with high seismic reflection amplitudes that are potentially caused by shallow gas (e.g., Jones et al., 2013).

Data

We used the BG1002R13 seismic reflection survey acquired by CGG and processed by BG Geophysical Operations in 2013. The data can be retrieved from the DISKOS database (https://portal.diskos.cgg.com/whereoil-data/). The survey is a 3D Narrow Azimuth (NAZ) seismic reflection survey acquired using a dual marine airgun source with 10 six-kilometre-long streamers and 480 receiver groups, defining a full-fold area of c. 1100 km^2. The group and flip-flop shot intervals were set to 12.5 m, whereas the spacing between cables was 100 m. A high-cut frequency filter of 200 Hz was applied along with a bandpass filter of 2-7 Hz. Additional filters and pre-processing steps applied to the raw data include swell noise attenuation and linear random de-noise with top and bottom mutes. The total recording length and initial sampling intervals are 5050 ms and 2 ms, respectively (Jones et al., 2013).

Various approaches were used to generate a good starting velocity model for the FWI, including a 1-D wellbore-derived blocky model, first arrival refraction tomography-based model and a constrained Dix inversion model of the stretched-to-depth pre-stack-time-migration root-mean-square velocity field (Jones et al., 2013). The FWI velocity model is then used to generate the final full-stack depth volume that runs from 0 m to 6000 m sampled every 10 metres. The data was processed using a zero-phase wavelet and displayed in reverse SEG polarity convention, i.e., a downward increase in acoustic impedance is

118 represented by a trough (coloured blue) and a decrease by a peak (coloured red). The seismic resolution

119 is 10- 70 m.

120 In this study, we also used data from wellbore 7224/7-1, which was drilled in 1988 to evaluate the

121 hydrocarbon reservoir potential of the Lower Jurassic and Upper Triassic sandstones and to improve

122 previous structural and geophysical interpretations to better the understanding of the area (NPD, 2023).

123 The wellbore drilled a total depth of 3067 m and provides age and lithological constraints down to the

124 Lower Triassic (Olenekian). The age and lithological constraints allowed us to understand the character of

125 the seismic reflection data and FWI expression of the faults.

126 **Method**

127 Our results are derived from two main approaches: 1) seismic interpretation, and 2) statistical analysis of

128 seismically imaged fault properties, which we later consider in the context of the present regional stress

129 field and calculated SGR. First, we mapped horizons and faults and generated seismic attributes using

130 Petrel seismic interpretation software. In total, we mapped 15 horizons (11 tie to age-constrained

131 formation tops proven by wellbore 7724/7-1, one marks the top of the acoustic basement, and three

132 define regionally mappable intra-formational horizons; Fig. 1a). Our horizon mapping approach involved

133 a coarse, first-pass interpretation with an in-line and x-line spacing of 100 x 250 (i.e., 1250 m x 3125 m).

134 In areas where the seismic quality was poor or the reflections less-prominent and continuous, we mapped

135 the horizons every 32 and 50 in-lines and x-lines, respectively (i.e., 400 m x 625 m). After this initial

136 systematic mapping, we used 3D auto-tracking to populate the interpretation across the study area to fill

137 gaps in our grid. We then manually interpreted (at 12.5 m spacing) reflections into areas where auto-

138 tracking was not possible because they were discontinuous and characterised by low amplitude. In terms

139 of fault mapping, we generated a variance seismic attribute to highlight signal discontinuities in the

140 seismic reflection data (e.g., Randen et al., 2001). We computed the variance attribute for key depth slices

141 and along key horizons. The variance attribute helped reveal the fault network and aided fault mapping.

142 We also compared the variance attribute generated from the depth volume (PSDM) with variance time

143 slices computed from the time volume (PSTM); this helped ensure the fault network geometry was

144 consistently imaged and not unduly influenced by processing or depth conversion steps. Overall, we

145 mapped 48 faults by combining the variance data and seismic cross-sections taken perpendicular to the

146 local strike of each fault.

147 Following the seismic interpretation stage, we examined the FWI velocity volume to note any

148 lateral velocity changes that could relate to faults. To do this, we first compare FWI velocity in-line and x-

149 line sections with corresponding seismic reflection depth surfaces (Fig. 2). This step revealed the expected

150 general velocity increase with depth, but also shows some lateral changes in velocity along horizons and

151 other linear features that correlate with faults interpreted in the seismic reflection data. We then

152 extracted FWI velocity values along key horizons mapped in the PSDM volume (Figs. 3a, 4a). The two

153 velocity surfaces showed clearly defined linear features with different velocities compared to the

154 surrounding areas. These features align with mapped faults, which are observed in variance slices taken

155 along H3 and H7, extracted from both the FWI velocity and PSDM volumes (Figs. 3, 4). While the

156 application of the variance attribute on seismic reflection data (PSDM volume) detects edges or signal

157 discontinuities that are often correlated to faults (e.g., Randen et al., 2001), computing the variance of

158 the FWI volume highlights sudden changes in velocity. The application of the variance to FWI models is a

159 novel approach that has not been reported previously as far as we are aware and, in this study, we

160 attempted to test the reliability and performance of the variance on FWI models.

161 After visually confirming the correlation between the linear features in the FWI velocity volume

162 and the fault network mapped in the PSDM volume, we then extracted the velocity values from the FWI

163 model along each horizon as spatially positioned point data (i.e., XY coordinates with corresponding

164 velocity data), thus allowing us to quantify any potential relationship. We also extracted velocity data

165 along individual fault traces. This resulted in individual velocity datasets for each mapped fault and for

166 each horizon. Given the fault trace geometries from the previous step, we could then extract the velocities

167 for a defined fault zone width (i.e., fault damage zone; *sensu* Kim et al., 2004; Childs et al., 2009) and

168 compare them to velocities at a set distance around the fault zone (i.e., to capture the velocity of

169 unfaulted host-rock). In this study, we determined fault zone width from our mapped fault planes (i.e.,

170 the fault polygon width determined from our mapping of footwall and hangingwall cut-offs) and host rock

171 width of 200 m taken around the fault zone polygon (Fig. 5). To compare the velocities between the two,

172 we calculated and compared a moving average value for each. We also used representative strike-

173 perpendicular profiles to detect any changes in velocity across fault zones, given the lack of obvious

174 methods of determining the width of a fault zone using seismic reflection data and to account for any

175 uncertainty in our defined fault zones (see Fig. 7.g as an example).

176 Lastly, we generated a combined attribute by computing a dip-steered, discontinuity-enhancing

177 attribute from the FWI velocity volume and multiplying it by a PSDM variance volume. The newly

178 generated combined attribute helps in 1) highlighting the faults and 2) detecting whether the fault zone

179 velocity is higher (+) or lower (-) than the surrounding host rock velocity. We then compared the results

180 of our velocity analysis with regional present-day stress orientation and Shale Gauge Ratio (SGR) results

181 (Alghuraybi et al., 2023), which provide insights into fault sealing potential. A summary of the workflow

182 we used here is shown in Fig. 6.

Results

184 We studied a total of 48 faults and focused our analysis on the interval between H3 and H7 (Lower Jurassic

185 to Upper Cretaceous) (Fig. 1a). This is because most faults tip out upwards into Lower Cretaceous strata

186 and the resolution of the FWI velocity volume (as expected given the narrow-azimuth nature of these

187 data) drastically decreases below 1.5 km (Appendix 1). The upper 1.5 km portion of the FWI model

188 resolves linear features that are consistent with apparent faults on the corresponding PSDM seismic

189 sections (Fig. 2). These linear features appear to locally have higher or lower P-wave velocities, whereas

190 in other locations they appear to simply offset two blocks of different velocities (Fig. 2b).

191 By extracting the velocities on H3 and H7, we can see the general velocity trend in the area at

192 each structural level (Figs. 3a, 4a). Overall, we observe a general velocity decrease towards the centre of

193 the surface (i.e., towards the Samson Dome, where horizons generally become shallower; Figs. 3a, 4a).

194 The velocity decrease towards the Samson Dome is logical as shallower horizons are expected to have

195 slower velocities. This general observation provides confidence that the FWI velocity model is showing

196 useful information about rock properties. However, we can also detect faults dissecting the dome; these

197 are clearly defined by velocity characteristics that differ to their flanking host rock (Figs. 3a, 4a). The

198 geometry of the faults seen in the FWI velocity surfaces is consistent with that observed in the PSDM

199 variance surface (Figs. 3c, 4c). We also note that a variance attribute taken from the FWI velocity volume

200 detects some of the faults seen on the PSDM variance (Figs. 3b, 4b). Although this qualitative velocity

201 difference is apparent visually, one might argue that these differences are rather subtle and largely

202 dependent on the dynamic range of the colour scale used to display the FWI velocity surface. However,

203 the variance results demonstrate the ability of the FWI model to recover fault zones, as the same fault

204 patterns are extracted from two largely independent datasets (PSDM- produced solely from reflections

205 and FWI- driven largely by refracted arrivals). To supplement the variance analysis results, we next present

206 a detailed quantitative analysis of three selected faults from the studied fault network. We selected these

207 faults based on their strike, location relative to the dome, and kinematic history. These results are later

208 compared to regional stress data and traditional fault seal analysis (i.e., SGR).

209 Fault 23 (F23) strikes NW-SE and is c. 6 km long (Fig. 7). F23 has a clear fault expression on the

210 PSDM variance surfaces (Fig. 7b) and appears as a continuous zone of relatively low velocity on both FWI

211   velocity surfaces (Fig. 7c). Our combined fault zone velocity attribute shows F23 as a laterally continuous

212   band of blue colour (i.e., lower fault zone velocity; Fig. 7d). The cross-plot of FWI velocities in and around

213   F23 shows general agreement with the combined attribute results (Fig. 7d, e). However, our statistical

214   analysis of the velocities reveals greater along-strike heterogeneity, with local zones of relatively high

215   velocity occurring within the fault zone (Fig. 7f). For example, the SW end of F23 at the structural level of

216   H3 shows a higher velocity as indicated by the positive difference between fault zone and host rock

217   velocities (Fig. 7f.1). Similarly, at the structural level of H7, F23 appears to have a higher velocity towards

218   its north-western end, and generally shows more fluctuation or scatter in the velocity difference between

219   fault zone and host rock velocities at this structural level (Fig. 7f.2). These statistical differences can be

220   confirmed by closely examining the FWI velocity surfaces (Fig. 7c), where minor velocity changes along-

221   strike can be detected. Equally, variable velocity difference between fault zone and host rock velocities

222   observed in the velocity analysis of F23 might be attributed to the fact that the fault is at the edge of the

223   survey where the FWI model (and the PSDM) is more poorly constrained (Fig. 3c). These along-strike

224   velocity variations might be interpreted as a result of noise or data artefacts. However, we observe similar

225   velocity variations along faults which are not at the edge of the survey (Fig. 4.a). Therefore, it is more likely

226   that these variations in velocity along-strike of the fault are recoding a physical response that reflects

227   along-strike variations in fault displacement, fault zone width, and/or shale/clay smear content.

228   Unlike F23, Fault 30 (F30) is in the centre and is thus fully imaged within the dataset (Fig. 3c). F30

229   strikes ENE-WSE and is on top of the dome (Fig. 8). Even though we can see the expression of F30 on the

230   PSDM variance surfaces, we also note the complex and more highly discontinuous nature of the PSDM

231   variance surface at this location (Fig. 8b). This is likely a result of the highly faulted nature of the dome

232   crest, which can be seen by the PSDM variance slice in Fig. 3c. In terms of FWI velocities, F30 shows an

233   overall higher velocity compared to the host rock. We observe these high velocities in the FWI velocity

234   surfaces (Fig. 8c) and combined attribute (Fig. 8d). These observations are supported by our statistical

235   analysis that shows F30 to generally have higher velocities along the fault (Fig. 8e, f) and across the fault

236   (Fig. 8g). The fault zone velocity signature is much clearer in the case of F30 compared to F23, where the

237   velocity difference between the fault zone and host rock is largely positive along-strike of the former (Fig.

238   8f).

239   Finally, Fault 26 (F26) is in the SW of the study area, away from the dome (Fig. 3c). F26 strikes ESE-

240   WNW and is associated with several synthetic and antithetic faults in its hangingwall (Fig. 9a). F26 is clear

241   in the PSDM variance surfaces, although a NNW-trending background fabric is also observed (Fig. 9b). This

242   fabric might be an acquisition footprint as it is aligned with the direction of the survey in-lines (see

243   orientation of the blue dashed line in Fig. 1c). Unlike F23 and F30, F26 has different velocity expressions

244   at the structural levels of H3 (i.e., low) and H7 (i.e., high) (Fig. 9c). The variable velocity with depth is also

245   observed in the combined attribute, which defines F26 as a strong, laterally continuous red (positive) band

246   at H7 level (Fig. 9d.2), whereas a generally blue, relatively less laterally continuous band is observed at

247   the structural level of H3 (Fig. 8d.1). The dual behaviour of the fault zone is confirmed by our statistical

248   analysis that shows F26 at the structural level of H3 is defined by velocities that are distinctively lower

249   than surrounding host rock velocities (Fig. 9e.1, f.1). In contrast, at the structural level of H7, our statistical

250   analysis confirms the overall higher velocity character shown by the other analysis, but also reveals more

251   along-strike variability (Fig. 9e.2, f.2).

252   **Discussion**

253   We document changes in fault zone velocities that can be discerned both qualitatively (i.e., by visually

254   examining velocity slices) and quantitatively (i.e., by extracting fault zone velocities and comparing them

255   to surrounding velocities). Our results confirm that an FWI velocity model is capable of detecting fault

256   zones (down to depth 1.5 km in our study area, limited only by a 6 km streamer length) as shown by the

257   FWI variance that closely resembles the structures highlighted by the more traditional, PSDM variance

258   slice (Figs. 3; 4). Along with detecting faults zones, the FWI velocity volume also captures variations in the

259   physical properties of individual faults within the studied fault network and along-strike of individual

260   faults. These differences in P-wave velocity within fault zones may be related to the presence of gases or

261   fluids (i.e., gas clouds) potentially masking or amplifying velocity differences. Nonetheless, we argue that,

262   when combined with other analyses (i.e., structural, stratigraphic analysis using seismic reflection

263   datasets), FWI velocity models can reveal valuable information about the physical properties of fault

264   zones. Mainly, we show that the FWI model shows differences in P-wave velocities among the studied

265   fault network, which might be valuable not only to predicting fault's sealing potential (e.g., Welbon et al.,

266   1997; Bailey et al., 2006), but also in capturing changes in fault zone architecture.

267   Across all scales, normal faults can have complex internal architecture, with variable fault core

268   width, continuity (continuous along fault zone or discontinuous and patchy fault zones) and multiple slip

269   surfaces (e.g., Michie & Haines, 2016). Previous studies show a range of factors can control fault zone

270   architecture, including fault growth history (e.g., Childs et al., 2009), host rock lithology, pre-existing

271   fabric, and the depth at which the fault is buried (e.g., see review by Wibberley et al., 2008). Laboratory

272   experiments have also demonstrated the rheological differences in fault rocks can also result in variable

273   fault strength and stability (e.g., Bedford et al., 2022). The geometry and internal architecture of fault

274   damage zones can also be controlled by slip mode at the fault's tips and the overall three-dimensional

275   geometry of the fault plane (e.g., Kim et al., 2004). Regardless of the exact mechanism that determines

276   fault zone architecture or extent of fault's damage zone, our current understanding of fault zone

277   properties supports their variable and heterogeneous nature. We propose that the P-wave velocity

278   anomalies we observe (Figs. 7-9) are likely a manifestation of the documented complexity of fault zone

279   architecture and fault damage zones (e.g., Kim et al., 2004; Wibberley et al., 2008; Childs et al., 2009;

280   Michie & Haines, 2016). Furthermore, the P-wave velocity anomalies might also reflect variability in fault

281   seal condition within fault zones, which is something that needs to be considered in subsurface fluid flow

282   models (i.e., during the characterisation of CCS sites or geothermal exploration targets, for example).

283   Given the expected variation in P-wave velocities within faults zones, we investigate whether there are

284   any overall correlations between high/low P-wave velocity anomalies with: i) regional present-day stress

285   field and ii) conventional fault seal analysis results (SGR).

286   Previous studies in the Samson Dome have related fault opening and increased leakage to the

287   present-day stress direction for faults offsetting shallow strata on the crest of the dome (e.g., Mattos et

288   al., 2016). We hypothesise that faults that are likely leaking will show lower fault zone P-wave velocities.

289   As leaking faults are often associated with increased permeability and/or fluid content, which lowers their

290   P-wave velocities. By quantitively demonstrating the velocity differences between fault zones in the

291   Samson Dome, we show that, overall, faults that strike NW-SE (i.e., parallel to the present-day maximum

292   stress orientation; Heidbach et al., 2016) tend to have lower fault zone velocities (c. 3130 – 3140 m/s)

293   compared to their surrounding host rock (c. 3180 – 3200 m/s; Fig. 7). In contrast, faults that strike E-W

294   (i.e., perpendicular to the present-day maximum stress orientation) are characterised by higher fault zone

295   velocities (up to c. 80 – 120 m/s higher fault zone velocities compared to host rock velocities; Fig. 8).

296   However, our results also show that not all fault zone velocities of the studied fault network show a

297   relationship to the present-day maximum stress orientation. For example, Fault 26 trends perpendicular

298   to the present-day maximum stress orientation and instead of having higher fault zone velocities, shows

299   variable fault zone velocities across different structural levels (Fig. 9). This variability might relate to the

300   presence of interacting faults near the upper tip of the main fault.

301   Fault sealing potential and transmissibility are traditionally calculated using SGR (e.g., Manzocchi

302   et al., 2010; Yielding et al., 2010). In this study, we explore the correlation between SGR and the observed

303   P-wave velocity anomalies revealed by the FWI model. Alghuraybi et al. (2023) study the evolution of the

304   Samson Dome fault network and calculated SGR. They show that the studied fault network can be

305   subdivided into two main subgroups: i) faults with vertical linkage and ii) faults that show no evidence of

306   vertical linkage. The faults that show vertical linkage are generally associated with lower SGR (i.e., more

307   likely to be leaking than sealing). These faults include F23, which we show here to have lower fault zone

308   velocities across both H3 and H7 stratigraphic levels (Fig. 7). In contrast, F26 shows no evidence of vertical

309   linkage and exhibits higher SGR values than F23 (Alghuraybi et al., 2023), which we show has higher fault

310   zone velocities across the H7 stratigraphic level (Fig. 9.e2-g2). However, across the H3 stratigraphic level,

311   F26 shows lower velocities than surrounding host rock (Fig. 9.e1-g1). The inconsistency between velocities

312   across stratigraphic levels might hint at different factors controlling the studied fault zone properties, such

313   as the natural heterogeneity in fault zones observed in outcrops (e.g., Kim et al., 2004; Wibberley et al.,

314   2008; Childs et al., 2009; Michie & Haines, 2016). For instance, F26 has lower displacement at H3

315   compared to H7 (Alghuraybi et al., 2023). The lower displacement might result in thinner fault rock and

316   narrower damage zone (e.g., Childs et al., 2009) at the H3 stratigraphic level compared to H7 for F26.

317   Even though interpretation workflows using seismic reflection data have significantly improved

318   over the last decades (e.g., Jones & Knipe, 1996; Randen et al., 2001; Chopra & Marfurt, 2005; Fredman

319   et al., 2008; Braathen et al., 2009; Iacopini & Butler, 2011; Iacopini et al., 2016), given the nature of the

320   data used in these workflows, they are prone to be limited to only revealing fault geometries, fault facies

321   and generally improve the imaging and visualisation of the fault networks. Our results demonstrate the

322   potential of FWI models in recovering P-wave velocity within fault zones, which is something that cannot

323   be achieved by using seismic reflection data alone. We suspect that the recovered P-wave velocities within

324   fault zones are related to fault transmissibility. The variance attribute of the FWI model clearly highlights

325   locations of rapid changes in P-wave velocity that coincides with the location and geometry of distortions

326   in the PSDM volume, which we interpret as faults. However, not all of the faults we mapped in the PSDM

327   volume are seen in the FWI model (Fig. 10. a, b). This may be related to the fact that some fault zones are

328   too small to be resolved by FWI, or that some fault zones do not present as faster or slower velocity

329   anomalies compared to the surrounding host rock. Outcrop data of fault zone thickness and displacement

330   show a broad positive correlation between the two (e.g., Childs et al., 2009). Our results show that faults

331   that have weak or no FWI signature tend to have average displacements of < 12 m, whereas those clearly

332   visible on the FWI variance have an average displacement of c. 50 m (Fig. 10. c). We propose that by

333   incorporating the information from the FWI velocity models, we can increase the fidelity of our subsurface

334   interpretation by drawing from two separate datasets. Where two independent datasets converge, we

335   can have more confidence in our subsurface interpretations and resulting models. The increased reliability

336   is something that is needed, especially in the field of subsurface geoscience to help the community meet

337   energy transition policies and demands while providing essential public reassurance to the wider society

338   about future implementations of carbon capture and geologic storage, geothermal energy, radioactive

339   waste disposal sites, and mitigating seismic hazards. However, to fully test the hypothesis that FWI can

340   serve as a screening tool for fault transmissibility, it is crucial to obtain pressure data from sites of fluid

341   injection in the subsurface. This direct constraint on fault transmissibility would provide more conclusive

342   evidence.

343   **Conclusions**

344   Our study demonstrates the effectiveness of Full-Waveform Inversion (FWI) velocity models in recovering

345   the velocity structure of fault zones. By analysing the variance (i.e., edge attribute) of both the Post-Stack

346   Depth Migrated (PSDM) seismic reflection volume and FWI model, we observe 'edges' with identical

347   locations and geometries. These 'edges' correspond to locations of rapid changes in velocity and

348   distortions in post-stack seismic traces, which we interpret as faults. However, not all faults visible in the

349   PSDM are detectable in the FWI model. This discrepancy may be due to certain fault zones being too small

350   to be resolved by FWI or not exhibiting significant velocity anomalies compared to the surrounding host

351   rock. Many fault zones display variability in their P-wave velocity structure, reflecting the natural

352   heterogeneity observed in faults from outcrop studies. In the FWI model, some faults (or parts of faults)

353   appear as low-velocity anomalies, while others exhibit high velocities compared to the host rock. We

354   hypothesise that this variability may be attributed to fault transmissibility. Furthermore, there is a partial

355   correlation between fault velocity anomalies, the regional present-day stress field, and the results of Shale

356   Gouge Ratio (SGR) analysis. However, it is important to acknowledge the presence of large uncertainties

357   in the SGR analysis, which may limit its ability to provide a reliable indication of fault transmissibility in

358   the Samson Dome. To fully test our hypothesis, we need more data (i.e., pressure and core data) from

359   wellbores that are drilled across some of the faults where the FWI model exists to test predictions of fault

360   transmissibility derived from FWI P-wave velocity models. Nonetheless, the results from our study are

361   promising in terms of the effectiveness of FWI as a tool to predict physical properties of fault zones.

509 **Figure 1. (a)** Stratigraphic column summarising the seismic stratigraphic framework and horizon names
510 and ages as constrained by wellbore 7224/7-1. **(b)** Location map for the study area. **(c)** Depth map at the
511 H3 level highlighting the outline of the Samson Dome and some of the faulting in the area. The location
512 of wellbore 7224/7-1 is denoted by a blue star and the blue and red dash lines outline the location of
513 the depth and FWI sections shown in Fig. 2.

514 **Figure 2.** Representative in-line **(a)** and cross-line **(b)** with FWI data (top) and seismic reflection depth
515 data (bottom). The sections show the faulted nature of the area that can be seen in both FWI and depth
516 sections. Also, these sections highlight the lateral velocity changes across faults especially in **(b)**. The
517 dashed circle shows a case where a fault is offsetting two blocks of different velocities while the dashed
518 rectangle highlights faults with apparent detectable fault zone velocities that are different than adjacent
519 strata.

520 **Figure 3. (a)** FWI velocity data extracted along the L. Cretaceous H3 surfaces showing a general decrease
521 in velocity towards the centre (towards the dome) but also highlights velocity variations along and
522 across faults. **(b)** FWI variance attribute revealing some of the faults. The geometry of the fault network
523 can be seen clearly by the variance surface extracted along the H3 level **(c)**.

524 **Figure 4. (a)** FWI velocity data extracted along the L. Jurassic H7 surfaces showing a general decrease in
525 velocity towards the centre (towards the dome) but also highlights velocity variations along and across
526 faults. **(b)** FWI variance attribute revealing some of the faults. The geometry of the fault network can be
527 seen clearly by the variance surface extracted along the H7 level **(c)**.

528 **Figure 5.** A cartoon illustration of the fault zone velocity extraction methodology used in this study.

529 **Figure 6.** A summary of the workflow used in this study to map and analyse the fault network
530 and FWI velocity variations.

531 **Figure 7. (a)** a cross-section view of fault 23 using FWI (a.1) and PSDM (a.2) data. **(b)** A variance
532 slice showing the lateral extent and geometry of fault 23 along H3 (b.1) and H7 (b.2) levels. The
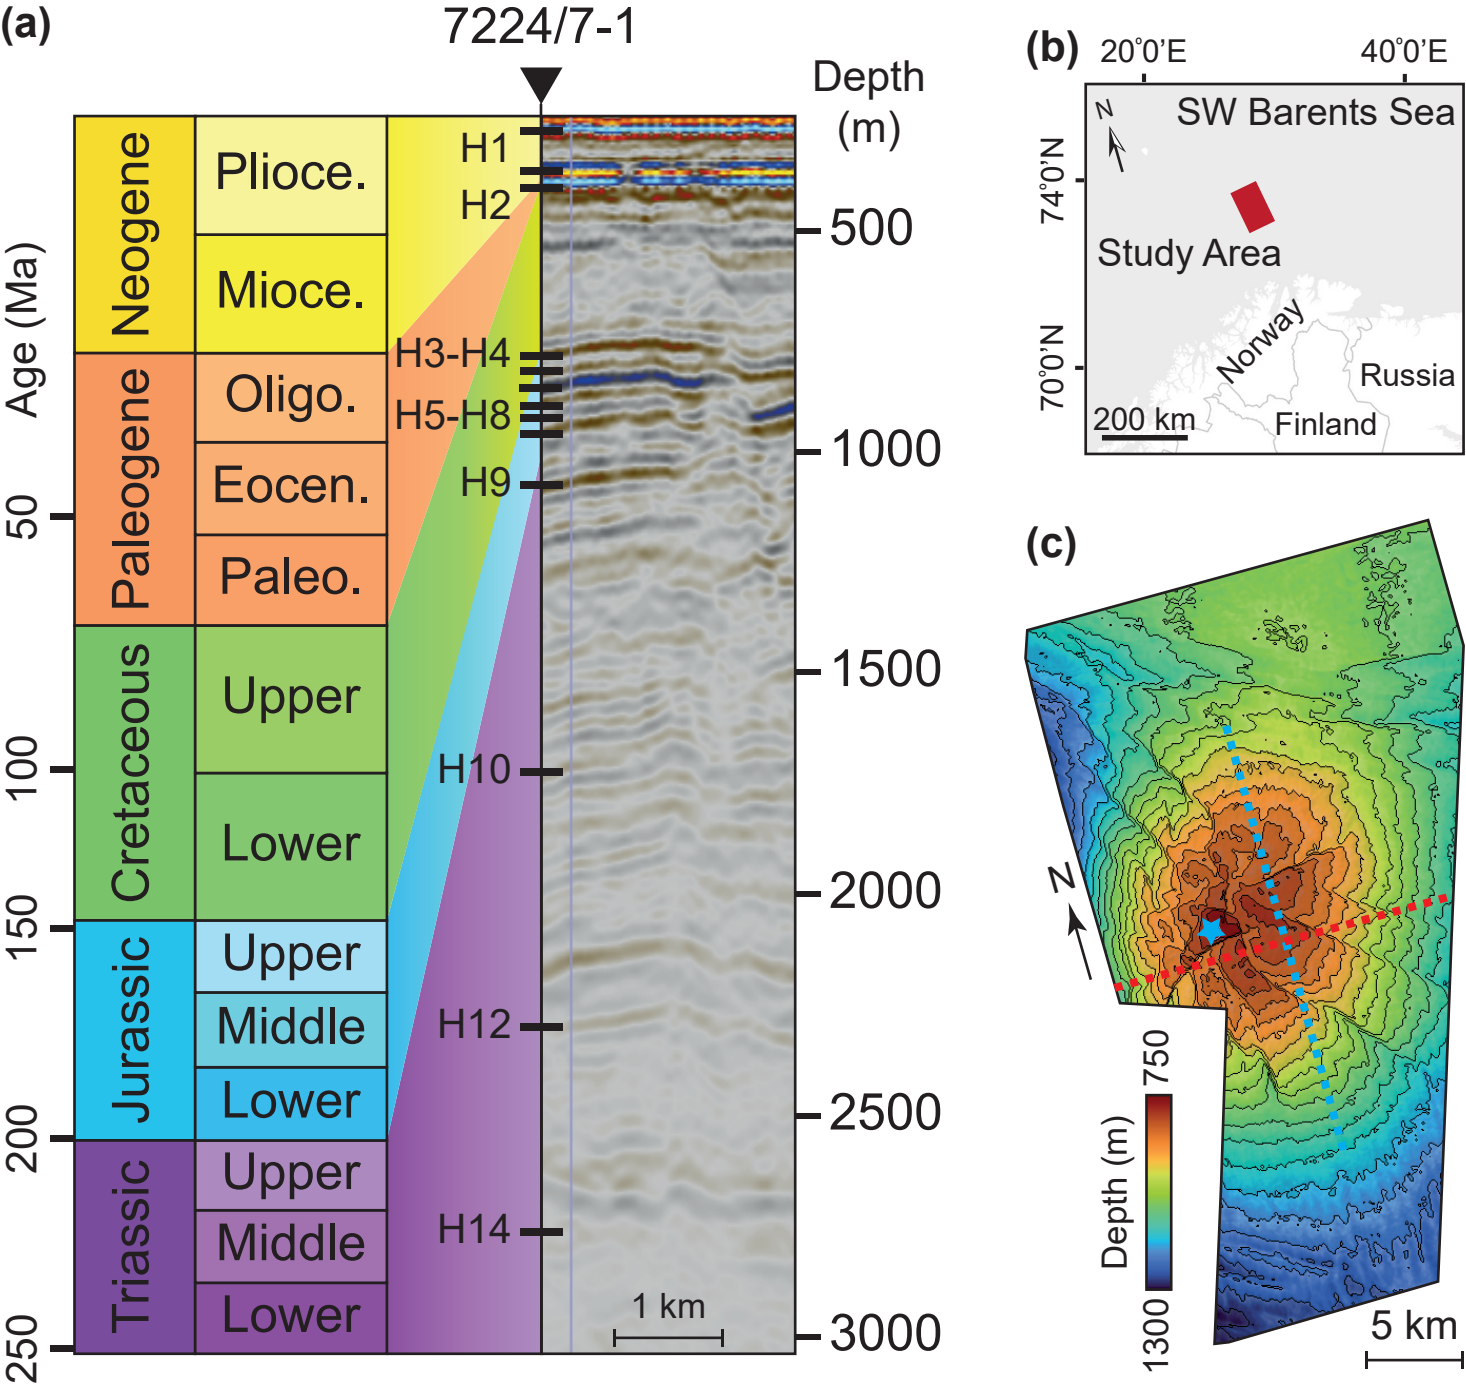

533   yellow dashed line in (b.1) shows the location of the cross sections in (a) and velocity profile in
534   (g). **(c)** FWI slices showing the velocity differences between the fault zone and surrounding
535   area. **(d)** Velocity detection attribute showing lower fault zone velocity on both H3 (d.1) and H7
536   (d.2) levels. The results from **(d)** are compared with quantitative analysis of the fault zone
537   velocity along the fault **(e & f)** and across the fault **(g)**. Fault zone velocities are shown in blue
538   while host rock velocities are shown in grey colour in **(e). (f)** shows the difference between the
539   two velocity categories. The location of the fault zone is shown by the shaded yellow colour in
540   **(g)** and the length of the profile is denoted by L**.**

541   **Figure 8. (a)** a cross-section view of fault 30 using FWI (a.1) and PSDM (a.2) data. **(b)** A variance
542   slice showing the lateral extent and geometry of fault 30 along H3 (b.1) and H7 (b.2) levels. The
543   yellow dashed line in (b.1) shows the location of the cross sections in (a) and velocity profile in
544   (g). **(c)** FWI slices showing the velocity differences between the fault zone and surrounding
545   area. **(d)** Velocity detection attribute showing higher fault zone velocity on both H3 (d.1) and H7
546   (d.2) levels. The results from **(d)** are compared with quantitative analysis of the fault zone
547   velocity along the fault **(e & f)** and across the fault **(g)**. Fault zone velocities are shown in blue
548   while host rock velocities are shown in grey colour in **(e). (f)** shows the difference between the
549   two velocity categories. The location of the fault zone is shown by the shaded yellow colour in
550   **(g)** and the length of the profile is denoted by L**.**

551   **Figure 9. (a)** a cross-section view of fault 26 using FWI (a.1) and PSDM (a.2) data. **(b)** A variance
552   slice showing the lateral extent and geometry of fault 26 along H3 (b.1) and H7 (b.2) levels. The
553   yellow dashed line in (b.1) shows the location of the cross sections in (a) and velocity profile in
554   (g). **(c)** FWI slices showing the velocity differences between the fault zone and surrounding
555   area. **(d)** Velocity detection attribute showing lower fault zone velocity on H3 (d.1) and higher
556   velocity on H7 (d.2) levels. The results from **(d)** are compared with quantitative analysis of the
557   fault zone velocity along the fault **(e & f)** and across the fault **(g)**. Fault zone velocities are
558   shown in blue while host rock velocities are shown in grey colour in **(e). (f)** shows the difference
559   between the two velocity categories. The location of the fault zone is shown by the shaded
560   yellow colour in **(g)** and the length of the profile is denoted by L**.**

561   **Figure 10. (a)** FWI variance attribute extracted along the H7 level. **(b)** The spatial distribution of
562   the studied fault network colour-coded by response strength on the FWI variance attribute.
563   Fault names are labelled on the map in (b). **(c)** Box plots showing the displacement distribution
564   of the faults grouped by strength of FWI variance signature.

Figure 1. (a) Stratigraphic column summarising the seismic stratigraphic framework and horizon names and ages as constrained by wellbore 7224/7-1. (b) Location map for the study area. (c) Depth map at the H3 level highlighting the outline of the Samson Dome and some of the faulting in the area. The location of wellbore 7224/7-1 is denoted by a blue star and the blue and red dash lines outline the location of the depth and FWI sections shown in Fig. 2.
Figure 2. Representative in-line (a) and cross-line (b) with FWI data (top) and seismic reflection depth data (bottom). The sections show the faulted nature of the area that can be seen in both FWI and depth sections. Also, these sections highlight the lateral velocity changes across faults especially in (b). The dashed circle shows a case where a fault is offsetting two blocks of different velocities while the dashed rectangle highlights faults with apparent detectable fault zone velocities that are different than adjacent strata.
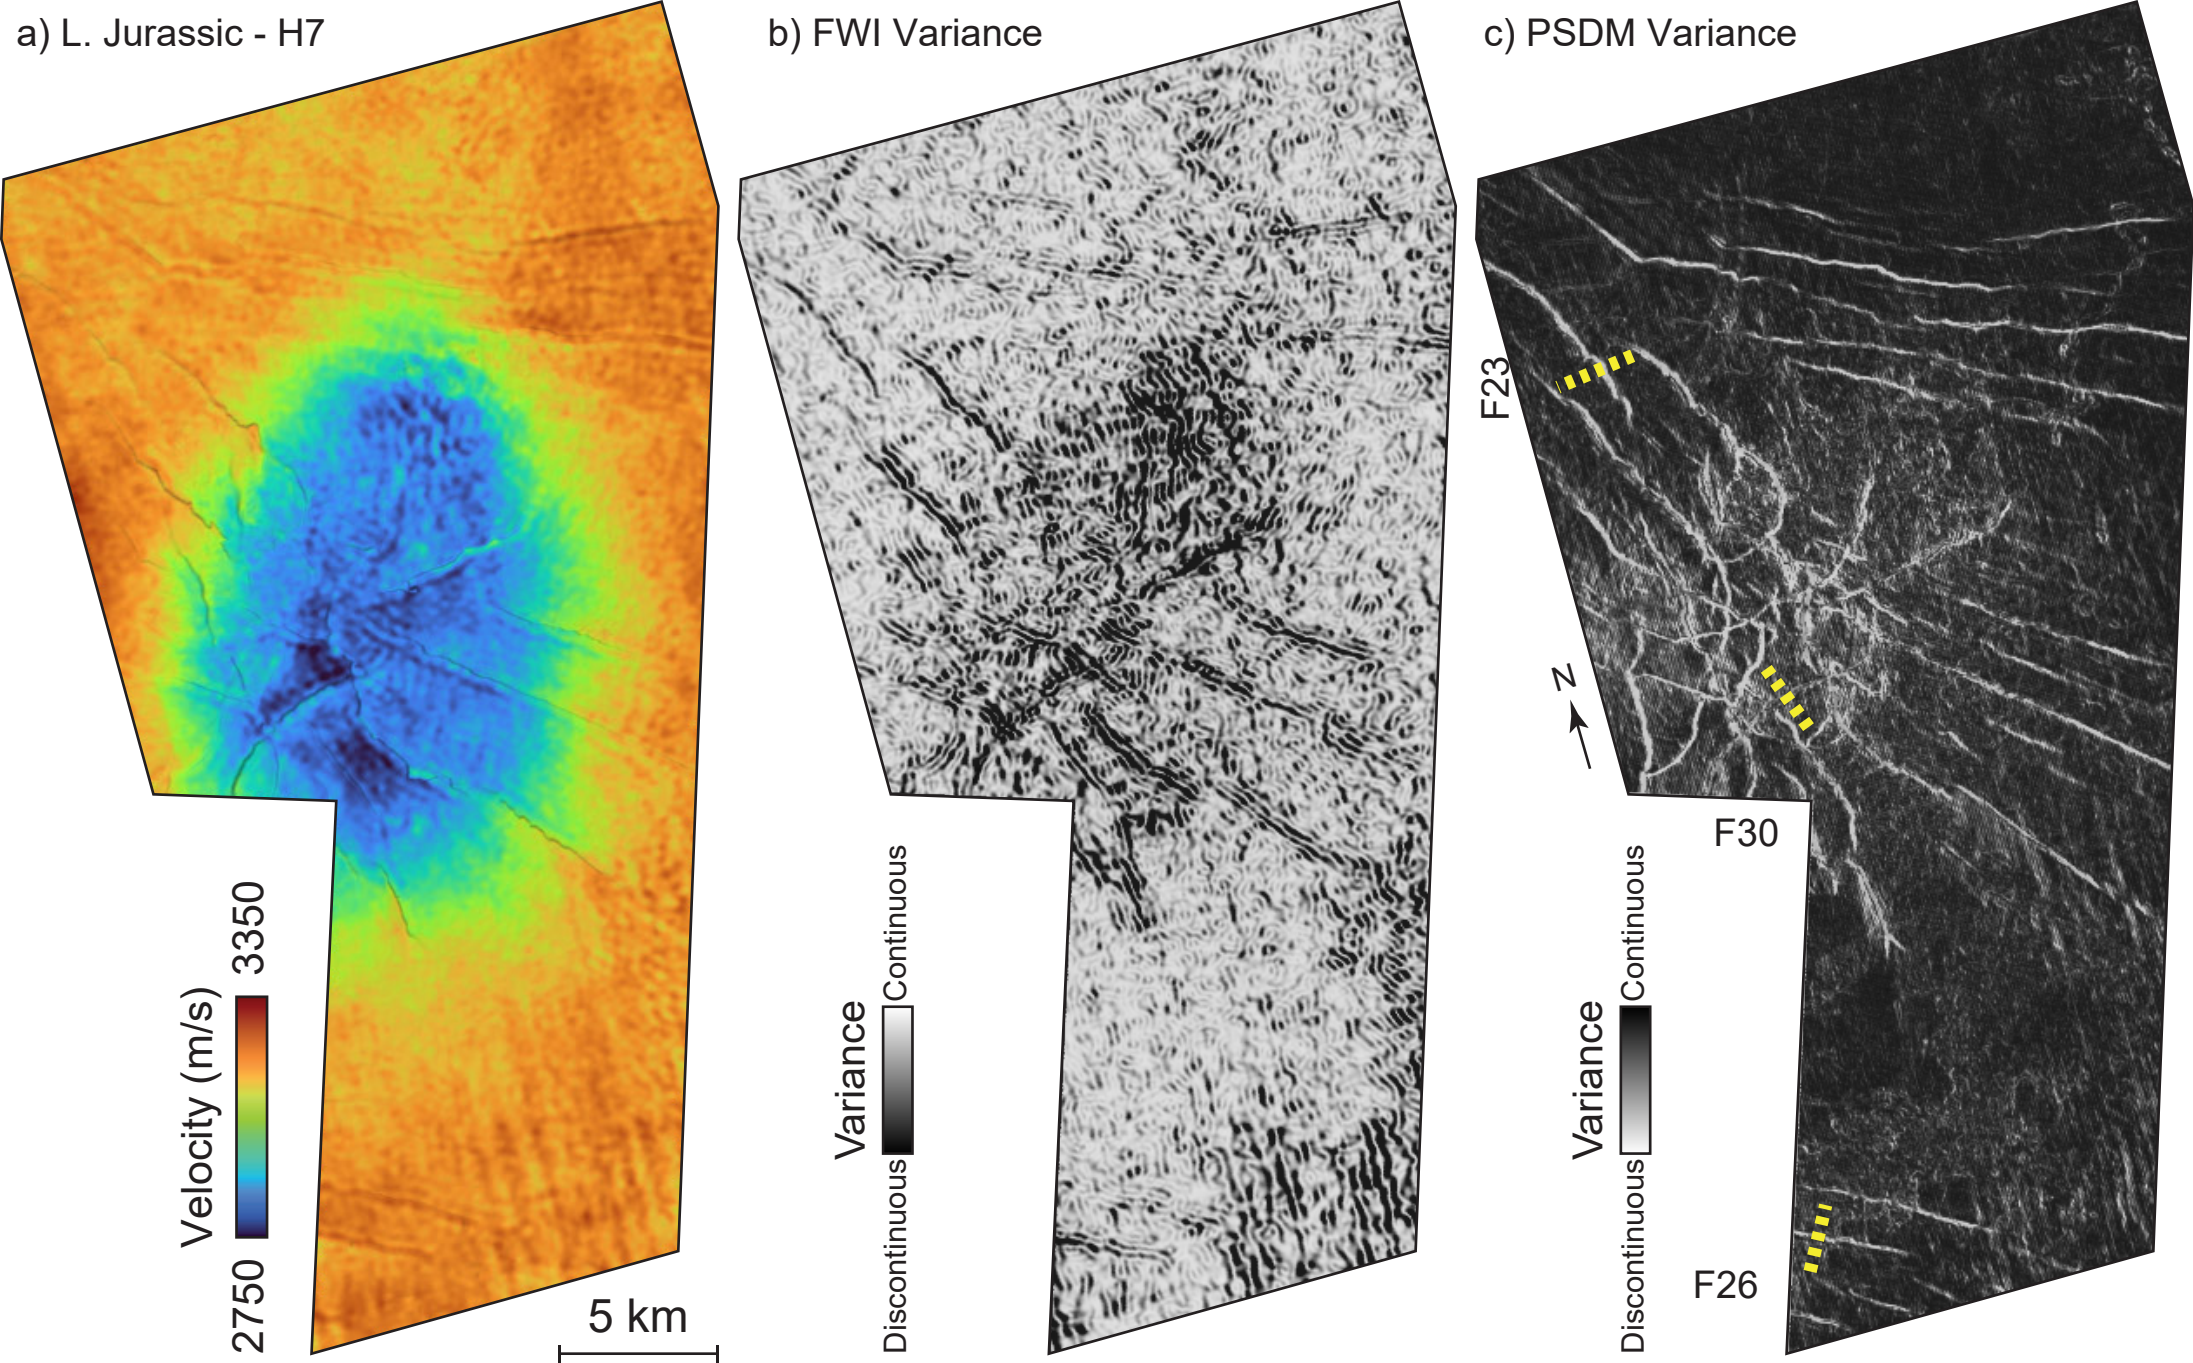

Figure 3. (a) FWI velocity data extracted along the L. Cretaceous H3 surfaces showing a general decrease in velocity towards the centre (towards the dome) but also highlights velocity variations along and across faults. (b) FWI variance attribute revealing some of the faults. The geometry of the fault network can be seen clearly by the variance surface extracted along the H3 level (c).
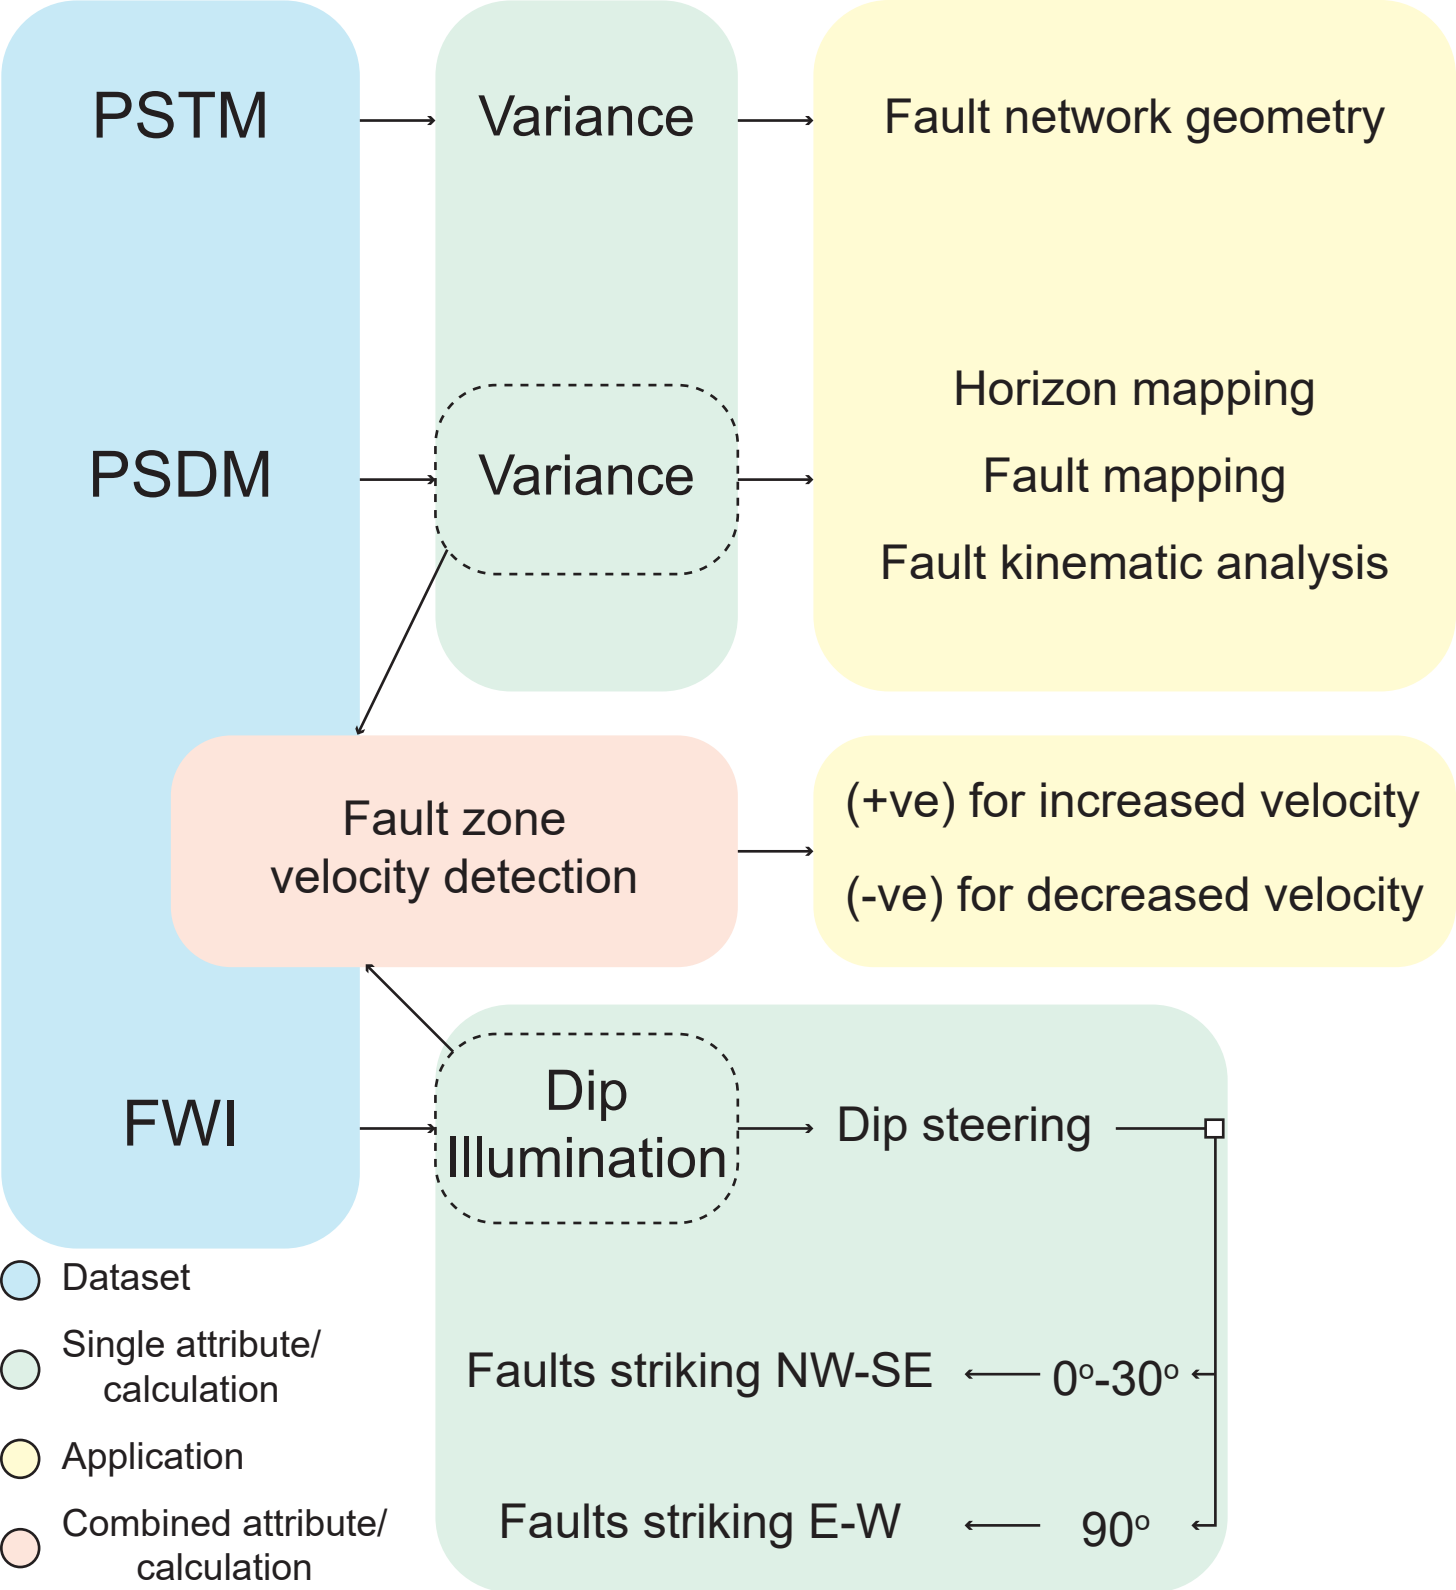

Figure 4. (a) FWI velocity data extracted along the L. Jurassic H7 surfaces showing a general decrease in velocity towards the centre (towards the dome) but also highlights velocity variations along and across faults. (b) FWI variance attribute revealing some of the faults. The geometry of the fault network can be seen clearly by the variance surface extracted along the H7 level (c).

Figure 5. A cartoon illustration of the fault zone velocity extraction methodology used in this study.
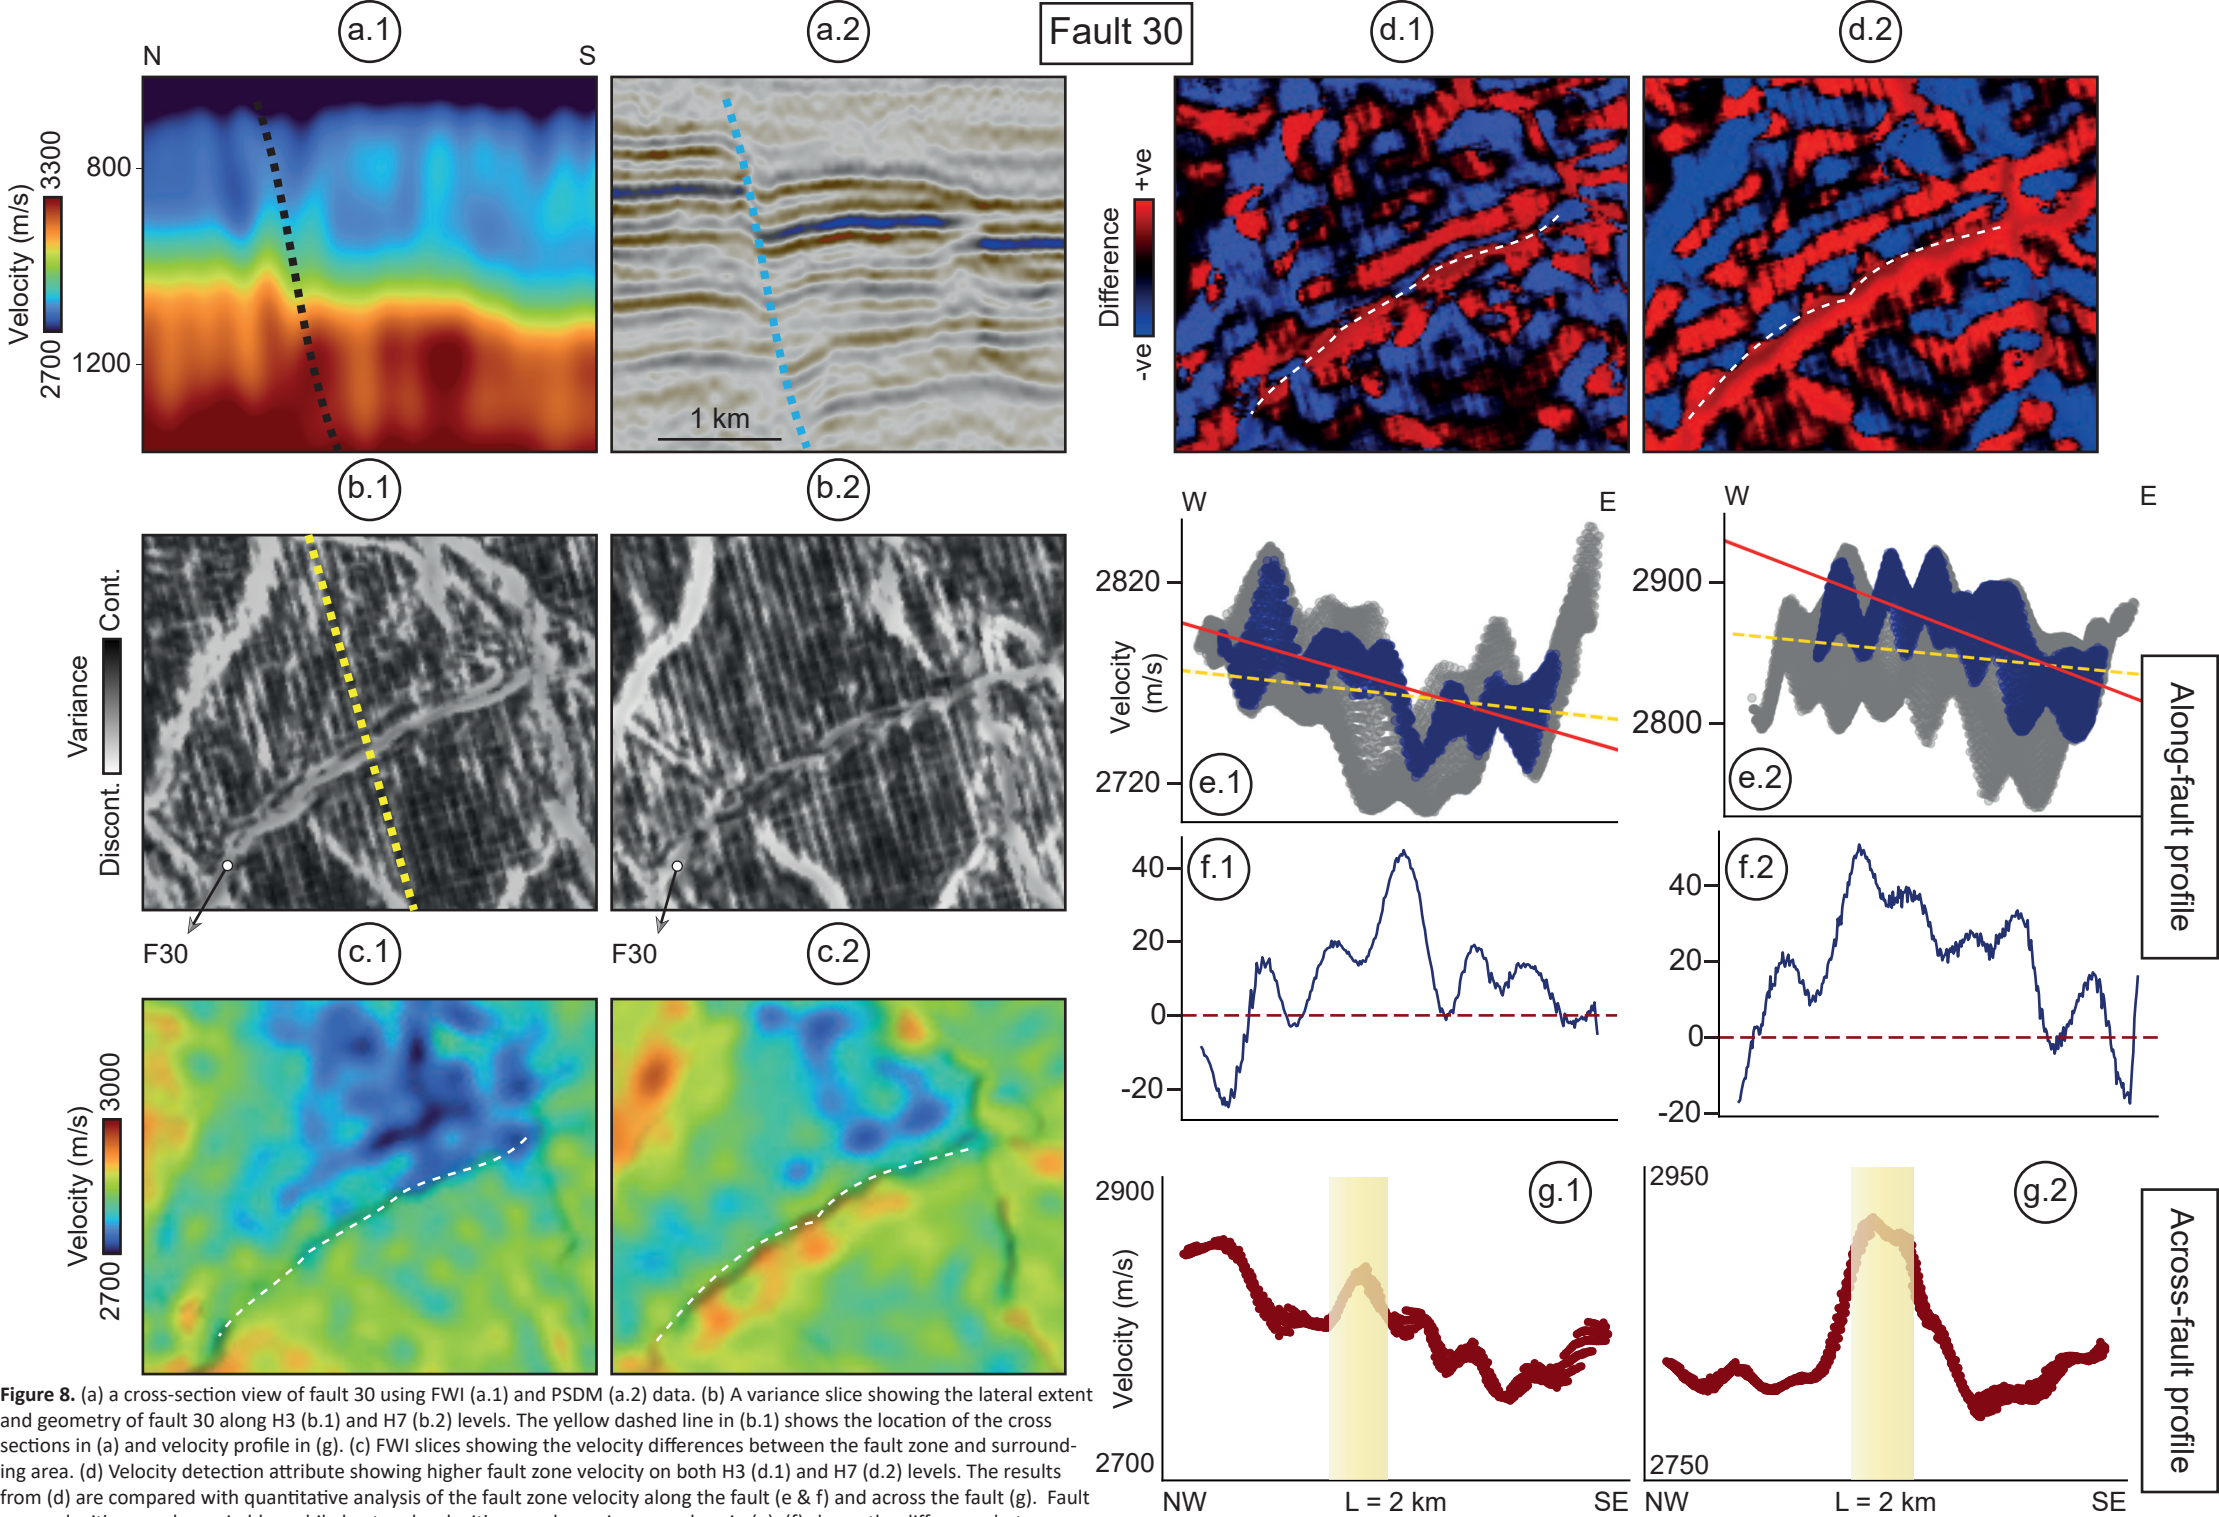

Figure 6. A summary of the workflow used in this study to map and analyse the fault network and FWI velocity variations.
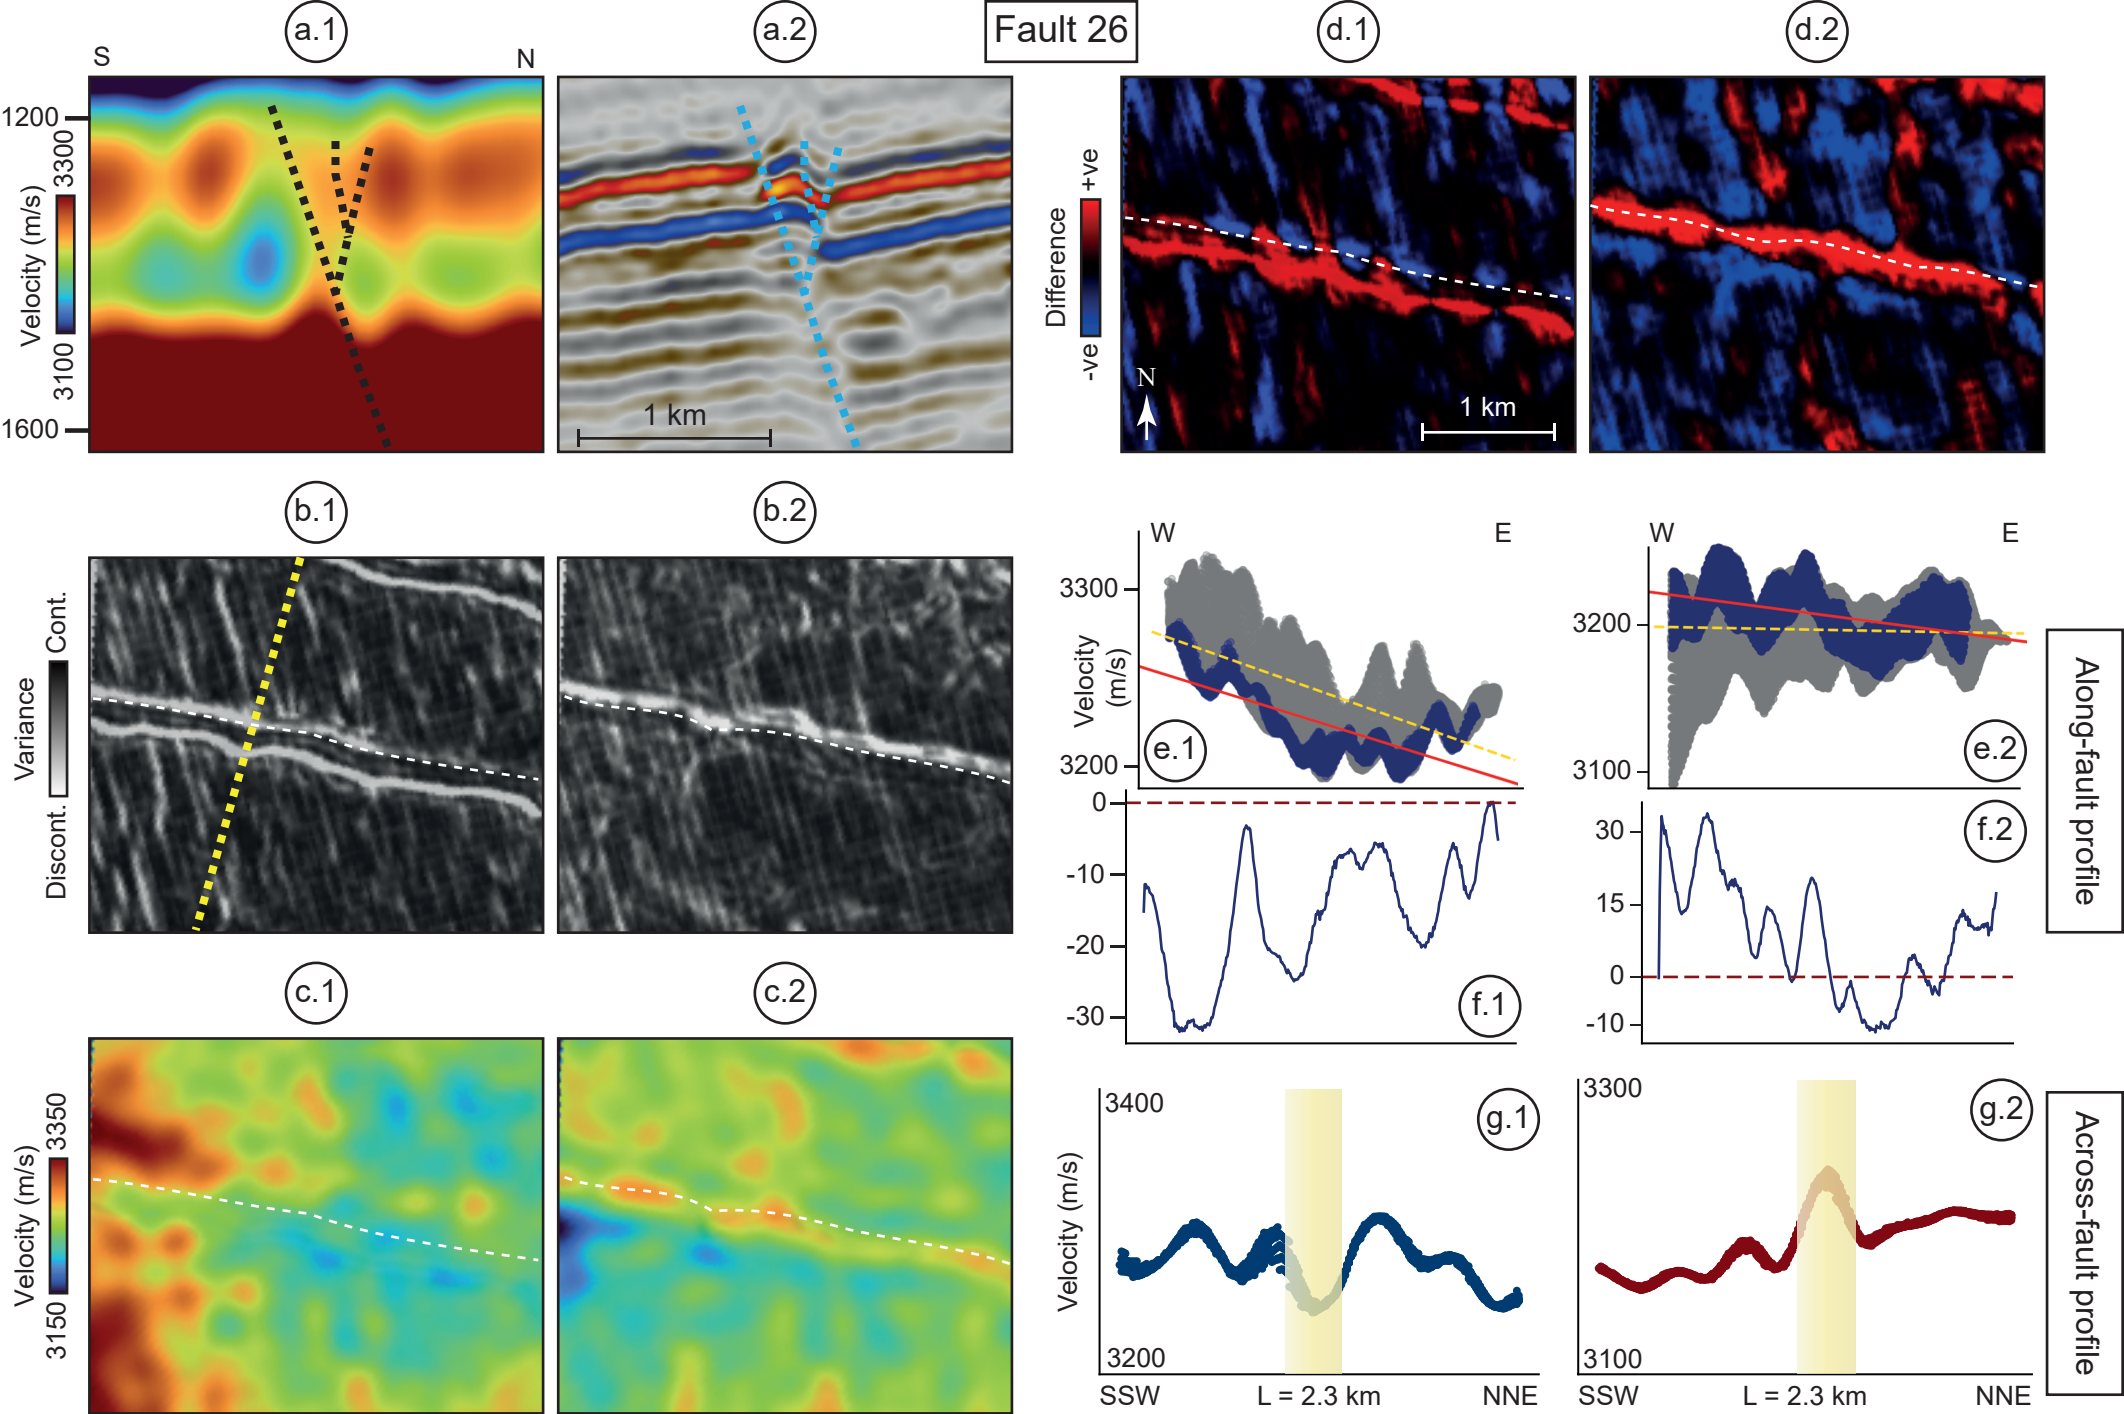

Figure 7. (a) a cross-section view of fault 23 using FWI (a.1) and PSDM (a.2) data. (b) A variance slice showing the lateral extent and geometry of fault 23 along H3 (b.1) and H7 (b.2) levels. The yellow dashed line in (b.1) shows the location of the cross sections in (a) and velocity profile in (g). (c) FWI slices showing the velocity differences between the fault zone and surrounding area. (d) Velocity detection attribute showing lower fault zone velocity on both H3 (d.1) and H7 (d.2) levels. The results from (d) are compared with quantitative analysis of the fault zone velocity along the fault (e & f) and across the fault (g). Fault zone velocities are shown in blue while host rock velocities are shown in grey colour in (e). (f) shows the difference between the two velocity categories. The location of the fault zone is shown by the shaded yellow colour in (g) and the length of the profile is denoted by L.

Figure 8. (a) a cross-section view of fault 30 using FWI (a.1) and PSDM (a.2) data. (b) A variance slice showing the lateral extent and geometry of fault 30 along H3 (b.1) and H7 (b.2) levels. The yellow dashed line in (b.1) shows the location of the cross sections in (a) and velocity profile in (g). (c) FWI slices showing the velocity differences between the fault zone and surrounding area. (d) Velocity detection attribute showing higher fault zone velocity on both H3 (d.1) and H7 (d.2) levels. The results from (d) are compared with quantitative analysis of the fault zone velocity along the fault (e & f) and across the fault (g). Fault zone velocities are shown in blue while host rock velocities are shown in grey colour in (e). (f) shows the difference between the two velocity categories. The location of the fault zone is shown by the shaded yellow colour in (g) and the length of the profile is denoted by L.
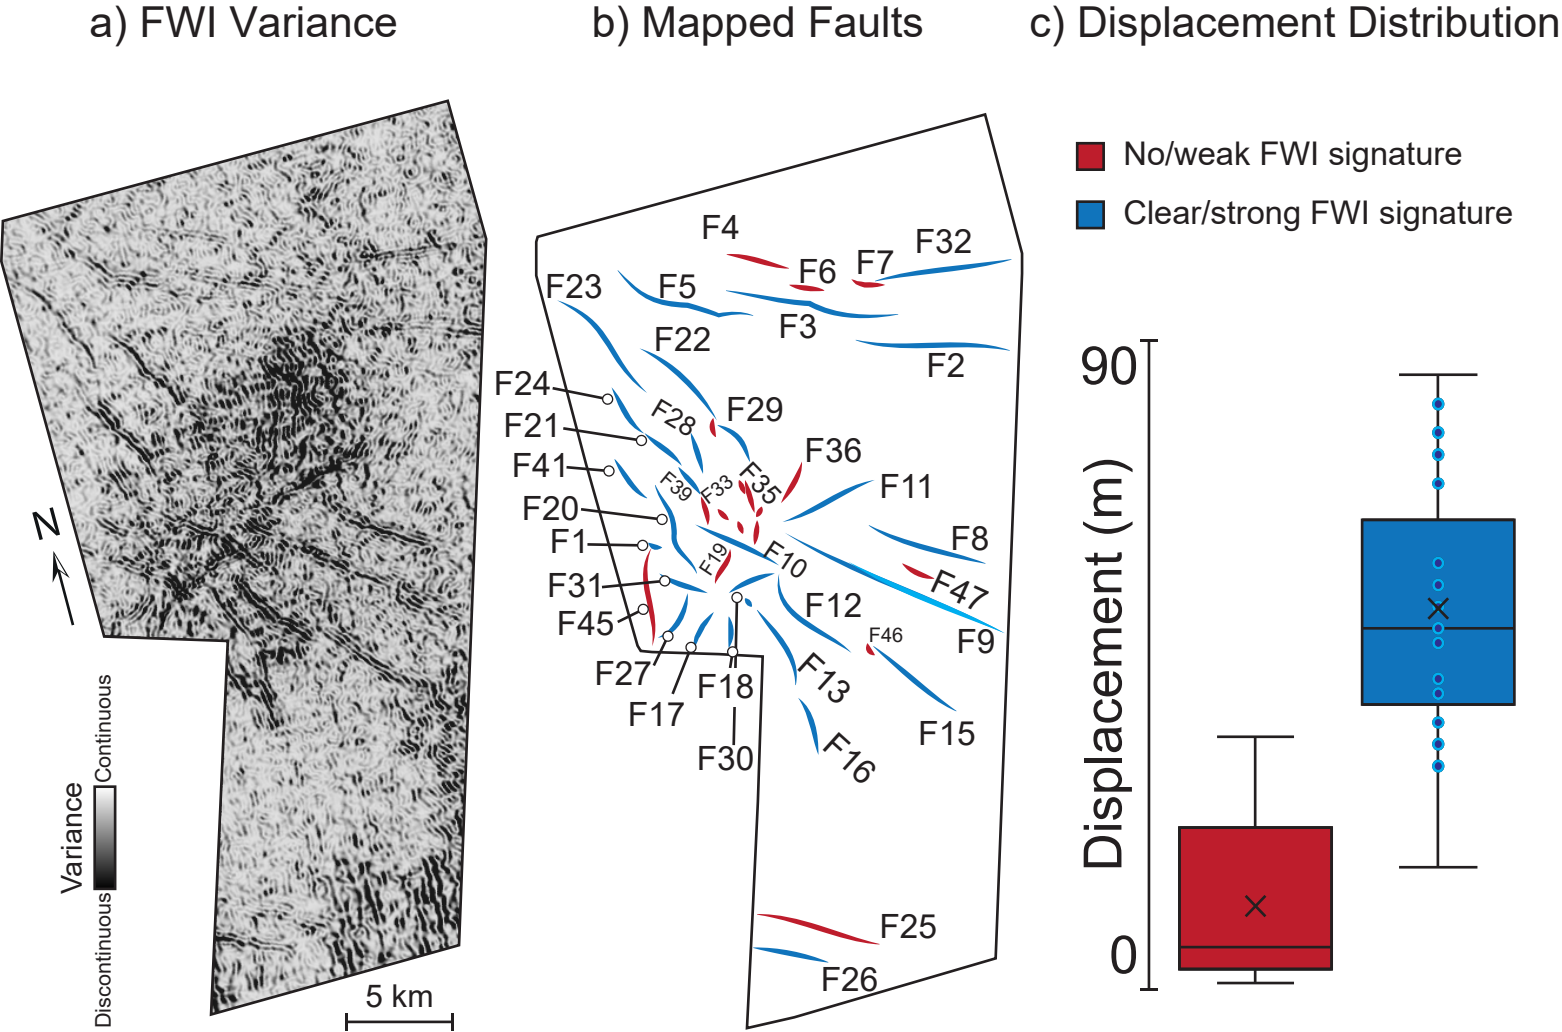

Figure 9. (a) a cross-section view of fault 26 using FWI (a.1) and PSDM (a.2) data. (b) A variance slice showing the lateral extent and geometry of fault 26 along H3 (b.1) and H7 (b.2) levels. The yellow dashed line in (b.1) shows the location of the cross sections in (a) and velocity profile in (g). (c) FWI slices showing the velocity differences between the fault zone and surrounding area. (d) Velocity detection attribute showing lower fault zone velocity on H3 (d.1) and higher velocity on H7 (d.2) levels. The results from (d) are compared with quantitative analysis of the fault zone velocity along the fault (e & f) and across the fault (g). Fault zone velocities are shown in blue while host rock velocities are shown in grey colour in (e). (f) shows the difference between the two velocity categories. The location of the fault zone is shown by the shaded yellow colour in (g) and the length of the profile is denoted by L.

Figure 10. (a) FWI variance attribute extracted along the H7 level. (b) The spatial distribution of the studied fault network colour-coded by response strength on the FWI variance attribute. Fault names are labelled on the map in (b). (c) Box plots showing the displacement distribution of the faults grouped by strength of FWI variance signature.
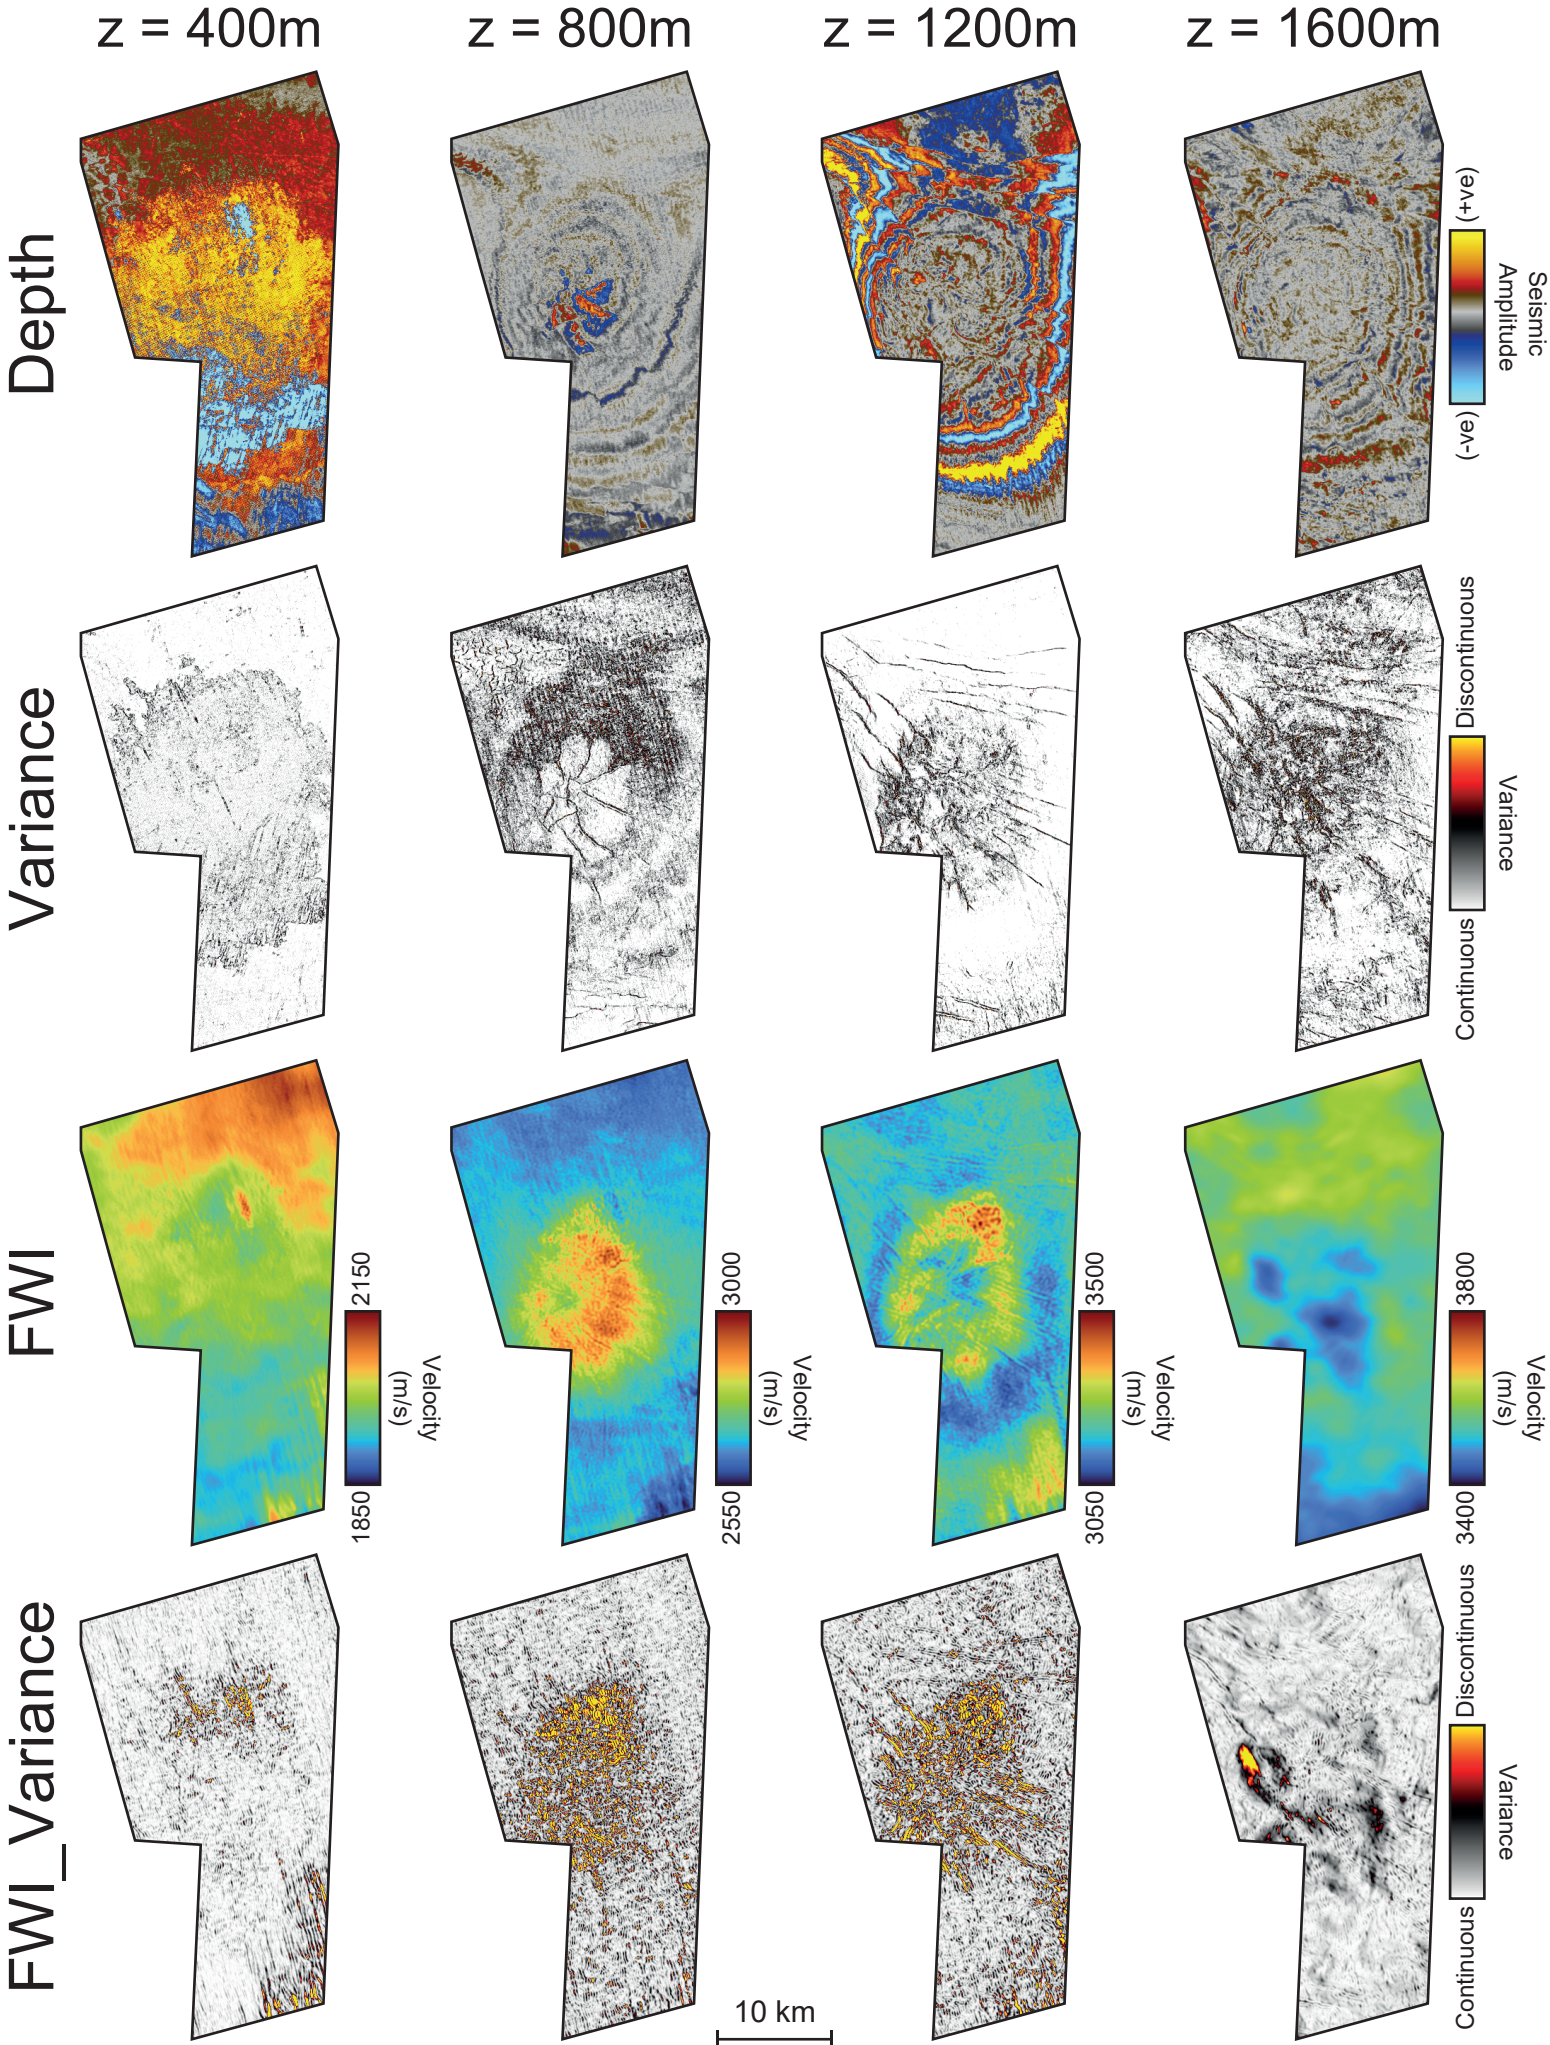

Appendix 1. Depth slices at 400 m, 800 m, 1200 m and 1600 m across the PSDM and FWI volumes and their associated variance attributes. These depth slices showcase the dramatic decrease in the FWI resolution after 1.5 km.
