Keywords:	Glacier surges, Remote sensing, Crevasses, Laser altimetry, Arctic glaciology
Abstract:	<p>The unique measurement capabilities of ICESat-2 allow high spatiotemporal resolution of complex ice-dynamic processes that occur during a surge. Detailed and precise mapping of height changes on surge glaciers has previously escaped observations from space due to limited resolution of space-borne altimeter data and the surface characteristics of glaciers during surge such as heavy crevassing. This makes geophysical interpretation of deformation and assessment of mass transfer difficult. In this paper, we present an approach that facilitates analysis of the evolution of geophysical processes during a surge, including height changes, crevassing, mass transfer and roughness evolution. We utilize all data from 2 years of ICESat-2 observations collected during the mature phase of the Negribreen Glacier System (NGS) surge in 2019 and 2020. The progression of the NGS surge has resulted in large-scale elevation changes and wide-spread crevassing making it an ideal case study to demonstrate ICESat-2 measurement capabilities, which are maximized when coupled with the Density Dimension Algorithm for Ice (DDA-ice). Results show the expansion of the surge in upper Negribreen which demonstrates the unique ability of ICESat-2/DDA-ice to measure a rapidly changing surge glacier and</p>

	provide the best estimates for cryospheric changes and their contributions to sea-level rise.

7 **ABSTRACT.** The unique measurement capabilities of ICESat-2 allow high
8 spatiotemporal resolution of complex ice-dynamic processes that occur during
9 a surge. Detailed and precise mapping of height changes on surge glaciers has
10 previously escaped observations from space due to limited resolution of space-
11 borne altimeter data and the surface characteristics of glaciers during surge
12 such as heavy crevassing. This makes geophysical interpretation of deformation
13 and assessment of mass transfer difficult. In this paper, we present an approach
14 that facilitates analysis of the evolution of geophysical processes during a surge,
15 including height changes, crevassing, mass transfer and roughness evolution.
16 We utilize all data from 2 years of ICESat-2 observations collected during
17 the mature phase of the Negribreen Glacier System (NGS) surge in 2019
18 and 2020. The progression of the NGS surge has resulted in large-scale
19 elevation changes and wide-spread crevassing making it an ideal case study to
20 demonstrate ICESat-2 measurement capabilities, which are maximized when
21 coupled with the Density Dimension Algorithm for Ice (DDA-ice). Results
22 show the expansion of the surge in upper Negribreen which demonstrates
23 the unique ability of ICESat-2/DDA-ice to measure a rapidly changing surge
24 glacier and provide the best estimates for cryospheric changes and their
25 contributions to sea-level rise.

26 1. INTRODUCTION

27 1.1. Glacier Surging: Relevance, Complexity and Observation from Space

28 Processes of ice-dynamic instability, such as glacial acceleration, have been identified by the
29 Intergovernmental Panel of Climate Change (IPCC, AR6, Chen and others (2021)) as a source of “deep
30 uncertainty” in our understanding of ice sheet and glacier evolution and their contribution to future sea-
31 level rise. Glacier surging is a type of glacial acceleration and is poorly understood due to surges being
32 relatively rare events with dramatic ice deformation occurring on short timescales resulting in a paucity of
33 comprehensive observations. The lack of surge observations, particularly those at resolution high enough to
34 resolve the complex surge processes, limits our community’s ability to analyze this important phenomenon
35 (Clarke, 1987; Truffer and Echelmeyer, 2003; Mayer and Herzfeld, 2000; Jiskoot, 2011; Herzfeld and others,
36 2013a).

37 A surge-type glacier will cycle quasi-periodically between a long quiescent phase of normal flow and a
38 short surge phase when flow speeds rapidly accelerate by a factor of 10 to 200. Negribreen, a large glacier in
39 eastern Spitsbergen, Svalbard, began to surge in 2016 for the first time in over 70 years (Lefauconnier and
40 Hagen, 1991; Strozzi and others, 2017; Herzfeld and others, 2021). Negribreen continues to surge through
41 2023, though it is gradually decelerating from its peak velocities in 2017 (Haga and others, 2020; Herzfeld
42 and others, 2022). A feed-back system of acceleration, crevassing and ice-ocean interaction has already led
43 to accelerated mass loss of the Negribreen Glacier System (NGS). There is a possibility that the Negribreen
44 surge may trigger pervasive mass loss and a potential disintegration of the entire glacier system, similar to
45 the collapse of the Vavilov Ice Cap in the Russian Arctic (Willis and others, 2018).

46 Surges are limited geographically to particular regions of the cryosphere, clustered mostly in
47 Alaska/Yukon, Svalbard, high mountain Asia and around the periphery of the major ice sheets (Dolgushin
48 and Osipova, 1975; Kamb and others, 1985; Kamb, 1987; Björnsson, 1998; Molnia and Post, 1995; Herzfeld
49 and Mayer, 1997; Mayer and Herzfeld, 2000; Murray and others, 2003; Björnsson and others, 2003; Truffer
50 and Echelmeyer, 2003; Jiskoot and others, 2003; Jiskoot, 2011; Flowers and others, 2011; Lee and others,
51 2013; Sevestre and others, 2015; Bhambri and others, 2017; Trantow and Herzfeld, 2018; Kochtitzky and
52 others, 2020; Vale and others, 2021; Banerjee and others, 2022; Yao and others, 2023; Guillet and others,
53 2022). While new satellite technologies have allowed detection of over 100 surge-type events from 2017-2022
54 (Kääb and others, 2023), very few of these events have received dedicated studies that map and document
55 individual surges making investigation of surge mechanisms and processes a data-starved problem.

56 Geophysical processes that are characteristic of a surge include rapid acceleration, crevassing, mass
57 transfer within the glacier, advance of the ice front, and changes in the internal hydrological system of the
58 glacier (Meier and Post, 1969; Kamb, 1987; Harrison and Post, 2003; Truffer and others, 2021). The first four
59 characteristics in particular are best and most directly observed with altimetry. However, observations of
60 surge glaciers from space are usually limited to radar imagery (e.g., Luckman and others (2002); Murray and
61 others (2003); Guan and others (2022); Wuite and others (2022); Kääb and others (2023)), which typically
62 focus on velocity analysis yet lack the spatial resolution to resolve crevasses, and field measurements (e.g.,
63 Kamb and others (1985); Björnsson and others (2003); Herzfeld and others (2013b, 2022)), which are rare
64 and often lack spatial and temporal coverage.

65 Detailed and precise mapping of height changes of surge glaciers has previously escaped observations of
66 space, because of limited resolution of space-borne altimeter data and heavy crevassing of the ice surface
67 as is characteristic during a surge. This makes geophysical interpretation of deformation and assessment of
68 mass transfer difficult.

69 In this paper, we present an approach that facilitates analysis of the evolution of geophysical processes
70 during a surge, including height changes, crevassing, mass transfer in the glacier and roughness evolution.
71 We utilize all data from 2 years of ICESat-2 observations collected during the mature phase of the
72 Negribreen surge in 2019 and 2020. The unique measurement capabilities of ICESat-2 allows resolution of
73 the complex ice-dynamic processes that occur during a surge in space and time in an altimeter data set.

74 1.2. The Study Area: Negribreen, Svalbard

75 The Negribreen Glacier System, a large glacier system in Arctic Svalbard (Figure 1(a)), surged in late 2016
76 reaching speeds of 21m/day during its peak in July 2017, equivalent to 200 times its normal quiescent
77 velocity (Strozzi and others, 2017; Herzfeld and others, 2021). In response to this rare event, the author's
78 Geomathematics, Remote Sensing and Cryospheric Sciences Group at the University of Colorado, Boulder,
79 conducted three airborne survey campaigns of the glacier system in the summers of 2017, 2018 and 2019
80 (Herzfeld and others, 2022), whose data supplements the analysis in this paper (see Section 2.2).

81 The NGS consists of Negribreen, where the majority of the surge activity occurs, Rembebreen, a southern
82 tributary glacier in the upper glacier system, and two main tributary glaciers flowing in from the north:
83 Akademikarbreen feeding Negribreen in the upper glacier, and Ordonnansbreen further down-glacier (Figure
84 2). The NGS receives large amounts of inflowing ice from the Filchnerfonna accumulation zone above the
85 NGS to the west. The divide between Filchnerfonna and the NGS as we have defined it in this paper

86 is somewhat arbitrary as the two ice masses are connected by a series of glaciers and ice falls (e.g.,
87 Transparentbreen) and are dynamically connected, which we show in this paper. However, the vast majority
88 of the surge activity, particularly in 2019 and 2020, occurs below the Filchnerfonna and as such we define
89 the bounds of the NGS using the black line in Figure 2, which excludes Filchnerfonna.

90 Negribreen consists of polythermal ice and is marine-terminating and thus the mechanisms leading to
91 surge behavior, along with surge evolution as a whole, differs from a surge in a temperate and/or land-
92 terminating glacier such Bering Glacier, Alaska (Dowdeswell and others, 1984; Murray and others, 2003;
93 Trantow, 2020). Similar to other observed surges in tidewater glaciers in Svalbard (Strozzi and others, 2017;
94 Nuth and others, 2019), Negribreen began accelerating near the terminus after a collapse in the frontal
95 area (location indicated in Figure 1(b)), and surge effects, such as crevassing and increased velocities,
96 propagated upglacier affecting other parts of the greater Negribreen Glacier System (Herzfeld and others,
97 2021; Haga and others, 2020). High velocities and enhanced calving occurring during the surge has led to
98 massive mass loss in the system, which has contributed to sea-level rise.

99 The mass loss and disintegration of the glacier system is immediately apparent by examining the time
100 series of Landsat-8 imagery in Figure 1 from 2018-2021 (RGB imagery at 30 m resolution, Roy and others
101 (2014)). The NGS terminus has seen massive deformation with the “tooth” of Ordonnansbreen becoming
102 completely detached from the main system by 2021 (see Fig. 1(e)). Detailed altimeter documentation of
103 the Ordonnansbreen tooth detachment is provided by the ICESat-2/DDA-ice time series in Section 4.3.3.

104 **1.3. ICESat-2 and the DDA-ice**

105 NASA’s ICESat-2 satellite, launched on 15 September 2018, provides high-resolution height measurements
106 of ice sheets and glaciers via its state-of-the-art micro-pulse photon-counting lidar technology (Markus and
107 others, 2017; Neumann and others, 2019). ICESat-2’s payload, the Advanced Topographic Laser Altimeter
108 System (ATLAS), provides height observations at 0.7 m along-track-resolution, a significant upgrade to its
109 predecessor, ICESat’s Geoscience Laser Altimeter System (GLAS), which provided height estimates every
110 173 m along-track from 2003-2009 (Zwally and others, 2002).

111 ATLAS operates at 532 nm (green light) and consists of 3 pairs of strong and weak beams with each pair
112 separated by 3.3 km in the across-track direction (Neumann and others, 2019; Martino and others, 2019).
113 Each strong beam is separated from its weak counterpart by 90 m across-track and 2.5 km along-track.
114 The ratio of transmit energies between strong and weak is approximately 4:1 in order to compensate for
115 varying surface reflectance. The transmitter array rotates its orientation approximately every 6-months so

Fig. 1. Landsat-8 images of the Negribreen Glacier System 2018-2021. Location of the Negribreen Glacier System (red box) within the Svalbard archipelago. Landsat-8 RGB imagery (30 m resolution) acquired (b) 2018-09-30 with the location of the surface collapse that initiated the surge circled in black, (c) 2019-08-20, (d) 2020-07-31 and (e) 2021-08-08 with Ordanonnsbreen's tooth indicated by the black arrow.

116 that either the weak beams lead (flying “forwards”, spacecraft orientation = 1), or the strong-beams lead
 117 (flying “backwards”, spacecraft orientation = 0)(see Figure 3 and Table 1 of Herzfeld and others (2021)).

118 ICESat-2 flies at ~ 500 km altitude and orbits in a 92° inclination, thus providing measurements up
 119 to $\pm 88^\circ$ latitude. The satellite flies in an exact 91-day repeat cycle and is divided into 1387 reference
 Cambridge University Press

120 ground tracks (RGTs) (Neumann and others, 2019, 2020b). All-in-all, ICESat-2 provides 6 measurement
121 opportunities across a 6.6 km swath every 70 cm along its flight path, repeating every 91-days.

122 Several factors limit the ideal spatiotemporal measurement resolution of ICESat-2 in the cryosphere,
123 the most significant being cloud cover through which green-light is severely attenuated. Other factors
124 contributing to weak or non-existent return signals over ice include diffuse scattering, the presence of water
125 or dirt, and pre-scheduled satellite maneuvers that either pause active measurement for maintenance or
126 calibration purposes, or point the instrument off its normal track in order to better capture a particular
127 phenomenon (Luthcke and others, 2021; Magruder and others, 2021). Signals are further complicated by
128 noise emanating from the solar background or from the instrument itself (Martino and others, 2019).
129 Furthermore, NASA's official ice-surface height product ATL06 (Smith and others, 2020), only resolves
130 surface heights with 40 m postings at 20 m spacing and does not take full advantage of the high-resolution
131 capabilities of ICESat-2 (Herzfeld and others, 2021).

132 The Density-Dimension Algorithm for Ice Surfaces (DDA-ice), however, fully exploits ICESat-2's
133 measurement capabilities by identifying height-signals at the native resolution of 70 cm (Herzfeld and
134 others, 2017, 2021). At this resolution, important geophysical processes can be measured such as crevassing,
135 calving and rifting (Herzfeld and others, 2021). In the present study, we employ the DDA-ice algorithm in
136 order to maximize ICESat-2's ability to capture geophysical processes in a rapidly changing glacier system
137 that is actively surging.

138 **2. DATA**

139 **2.1. ICESat-2 ATL03 Data**

140 The DDA-ice algorithm takes as input the ATLAS/ICESat-2 L2A Global Geolocated Photon Data (ATL03)
141 (Neumann and others, 2020b). We use release 4 (revision 1) of these data in this analysis (Neumann and
142 others, 2020a). The ATL03 data give height above the WGS 84 ellipsoid (ITRF2014 reference frame) along
143 with latitude, longitude and time for all the photons downlinked from ICESat-2.

144 ATL03 data are segmented by granules that each cover 1/14th of a single orbit. Granules are given
145 in HDF5 format and are freely available through NASA or from the National Snow and Ice Data
146 Center (NSIDC). Granules are named using the format ATL03_[yyyymmdd][hhmmss]_[ttttccss]_[vvv_rr].h5,
147 where [yyyymmdd][hhmmss] is the date and time of acquisition associated with the first data point in the

148 granule, [tttt] is the reference ground track (RGT) number, [cc] the cycle number, [ss] the segment number
149 and [vvv_rr] the version and revision numbers.

150 For our analysis of Negribreen, we attain all granules covering the NGS between 1 January 2019 and 31
151 December 2020. With the NGS lying between latitudes 78.5°N 78.8°N, the segment number is equal to
152 either 03 if the satellite as ascending during data collection or equal to 05 if the satellite is descending.
153 The cycle number identifies the number of 91-day cycles that have elapsed since ICESat-2 entered its
154 science orbit. Our analysis here uses data that spans eight cycles from cycle 02 to cycle 09. Each cycle
155 is divided into 1387 unique Reference Ground Tracks (RGTs). There are 9 RGTs that provide significant
156 data coverage of the NGS: 91, 152, 389, 450, 594, 831, 892, 1036 and 1334. Nine RGTs spanning 8 cycles
157 equates to 72 granules for this two-year analysis. With all six beams covering part of the glacier system
158 for each RGT, we process a total of 432 measurement passes in this analysis. The specific granules used in
159 this analysis are identified in the Supplementary Material (negri_data_2019_2020.xlsx).

160 ICESat-2's six beams are labeled as gt1l, gt2l, gt3l, gt1r, gt2r and gt3r. The strong beams can be
161 associated with either the left (l) or right (r) side depending on the orientation of the ICESat-2 observatory,
162 which switches every six months or so in order to maximize the solar illumination of the solar panels. At
163 the beginning of 2019, ATLAS was in its "backward" orientation with left ground tracks corresponding
164 to strong beams and right ground tracks corresponding to weak beams. ATLAS switched to its "forward"
165 orientation in September 2019 resulting in strong beam identification by the right ground tracks. A switch
166 back to the "backwards" orientation occurred in June 2020.

167 2.2. Airborne Altimeter and Image Data

168 We collected airborne altimeter data in the summers of 2017, 2018 and 2019 as part of a campaign to
169 document the surge of Negribreen (Herzfeld and others, 2022; Herzfeld and Trantow, 2021). Our analysis
170 here utilizes the data collected during the 2019 campaign, which under-flew several ICESat-2 tracks in
171 upper Negribreen on 13 August 2019.

172 For the 2019 campaign, height measurements were attained using a LaserTech Universal Laser System
173 (ULS) instrument that operates at 905 nm. The ULS was used in conjunction with a 1-Hz LORD 3DM-
174 GX5-15 Virtual Reference Unit, i.e. an IMU, along with a 10-Hz Trimble R10 rover GPS in order to attain
175 accurate height estimates. Both the ULS and GPS were attached the skids of a helicopter which was flown
176 100-200 m above the ice surface during operation of the laser. With an effective measurement rate of 400
177 Hz, the ULS provided glacier surface heights every 0.06-0.08 m along-track.

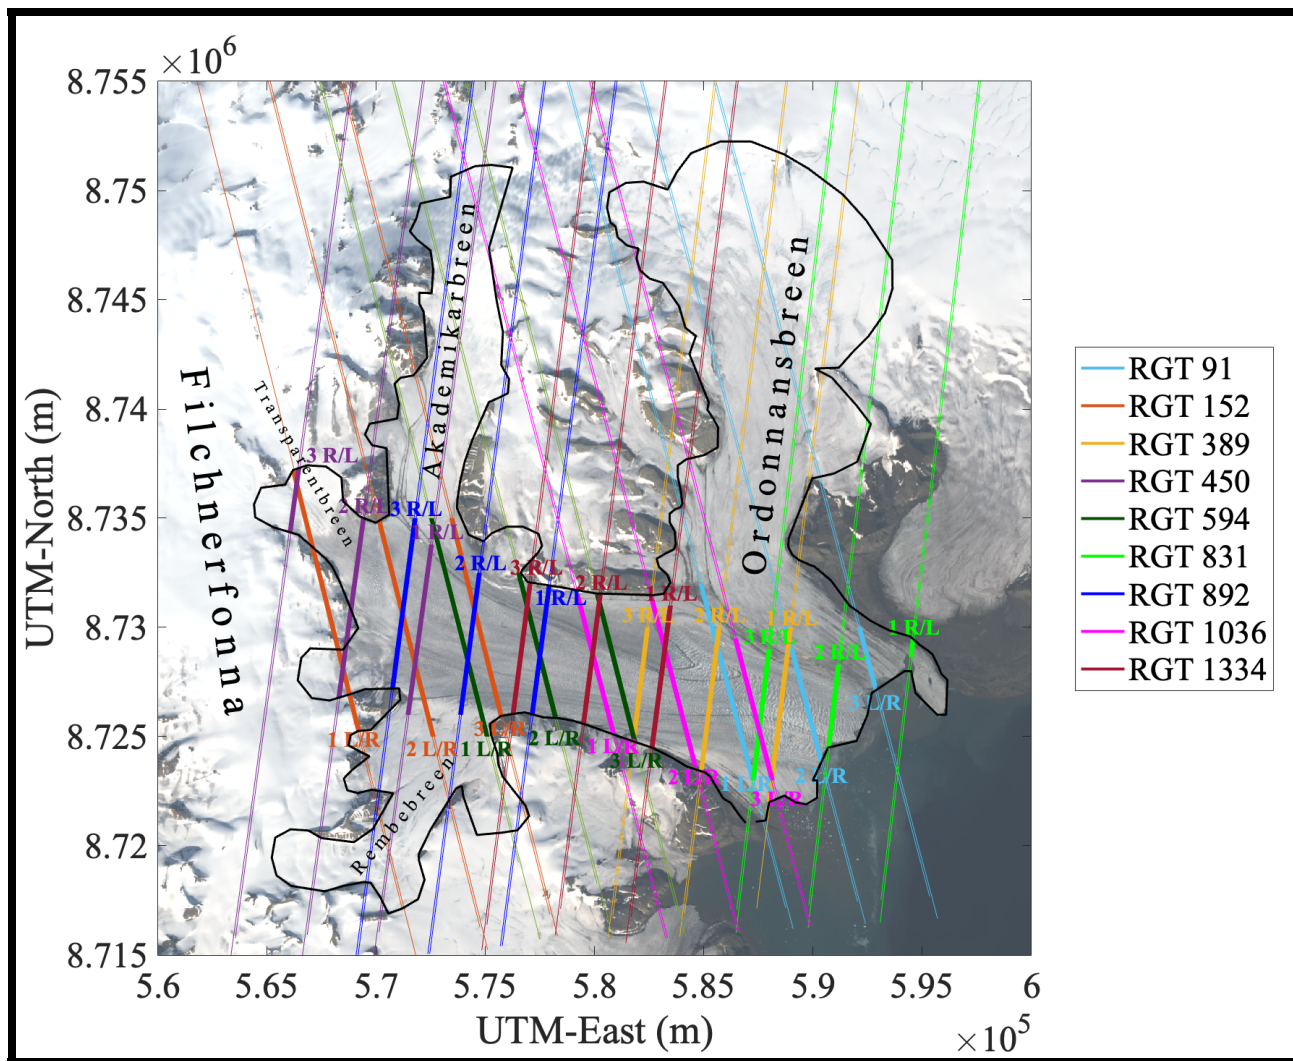

Fig. 2. ICESat-2 survey lines over the Negribreen Glacier System. The survey lines for each of ICESat-2's three beam-pairs are color coded by their Reference Ground Track (RGT) while the NGS borders are given by the black line. The thick lines correspond to the part of the track that is analyzed in this paper which is mostly equivalent to the boundaries of Negribreen Glacier. Left/Right (L/R) beam-pairs are separated by ~ 90 m on-ice which is within line thickness over Negribreen in this figure. Background image from Landsat-8 acquired 2019-08-05.

178 Specifically, the 2019 flight campaign under-flew two beam pairs: RGT 594 (gt1l and gt1r) from 5 August
 179 2019, and RGT 450 (gt1l and gt1r) from 18 August 2019 (Herzfeld and others, 2022). These two tracks
 180 passed over interesting crevassed areas in upper Negribreen (Fig. 2) and their dates of collection coincided
 181 with the field campaign. Crevasse characteristics along these tracks were quantified in Herzfeld and others
 182 (2021) and Herzfeld and others (2022) which found a close agreement between crevasse morphology, spacing
 183 and depth between ULS data and ICESat-2 data.

184 Selected photos from the 2019 campaign, taken with a handheld Nikon D5100 Single-Lens Reflex (SLR)
185 camera, are given in Figures 3 and 4. During the campaign in August 2019, much of the lower glacier
186 was covered in low-lying mixed-phase clouds (MPCs) (Shupe and others, 2006; de Boer and others, 2009;
187 Shupe and others, 2011; Gierens and others, 2020) (Fig. 3(a)). MPCs in Svalbard occur in every season
188 within 1 km of the surface, and have a complicated structure consisting of supercooled liquid and ice layers
189 that obviously obscure the glacier ice-surface (Gierens and others, 2020). These ephemeral low-lying clouds
190 restricted airborne surveys to the upper NGS for several, but not all, flights in 2018 and 2019.

For Peer Review

Fig. 3. Imagery from the airborne campaign flights over Negribreen in August 2019 (Part 1). (a) Low-lying clouds covering the lower glacier and terminus (photo looking downglacier, DSC_0753). (b) Young surge crevasses in upper Negribreen (acquired 13 August 2019, DSC_0898). (c) Large and complex crevasses exceeding 30 m depth in the center-front of the glacier just above the terminus (DSC_0422).

Fig. 4. Imagery from the airborne campaign flights over Negribreen in August 2019 (Part 2). (a) Snow-bridged crevasses seen most clearly in the left-foreground with the white, fresh snow covers the top of the open crevasses, DSC_0656. (b) Water-filled crevasses, DSC_0819. (c) Crevasses near the Negribreen-Akademikarbreen Medial Moraine (NAMM) are filled with water indicating a disruption in the local englacial drainage system, DSC_0344. Fresh crevassing through surge expansion affected this area along the northern NAMM in early 2020, shortly after this photo was taken.

191 2.3. Sentinel-1 SAR Data

192 We used Synthetic Aperture Radar (SAR) imagery from the European Space Agency's (ESA's) Sentinel-1
193 satellite (Geudtner and others, 2014) to derive velocity estimates on Negribreen. Mean velocity estimates
194 are derived for several characteristic time periods between 2019 and 2020 which are used to supplement
195 the ICESat-2 analysis by providing basic information on changes in the velocity field associated with the
196 surge.

197 There are two Sentinel-1 satellites labeled A and B, which in tandem provide repeat imagery every 6-
198 days for a given location. ESA freely provides the Sentinel Application Platform (SNAP) software to derive
199 surface velocity estimates for ice sheets and glaciers using offset tracking methods. Offset tracking methods
200 measure feature motion between two images using patch intensity cross-correlation optimization.

201 Over Negribreen, Sentinel-1 operates in the Interferometric Wide (IW) swath mode acquiring data with
202 a 250 km swath at 5 m by 20 m spatial resolution. The SNAP toolbox offset tracking method takes as
203 input the Level-1 Ground Range Detected (GRD) product from two Sentinel-1 images. These images are
204 separated by a temporal baseline, which in our analysis is usually equal to 12-days, i.e. the length the
205 repeat cycle of a single Sentinel-1 satellite. The GRD products are updated with more accurate orbit
206 data and are then coregistered based on geometry given by the ACE-30 Digital Elevation Model (DEM).
207 We then perform offset tracking providing a 300 m by 300 m resolution velocity product with missing or
208 low-confidence data interpolated up to 1 km.

209 Four characteristic velocity maps from 2019 to 2020 are provided in Figure 5. It is clear in each map
210 that Negribreen is surging, reflected by elevated speeds (> 1 m/day), while the tributary glaciers remain at
211 typical quiescent speeds well below 1 m/day. Velocity magnitudes are largest near the front of Negribreen
212 and decrease across its length with elevated speeds still present near the border with Filchnerfonna in the
213 upper glacier.

214 Figure 5(a) displays mean velocity magnitudes near the beginning of our study period between 2019-01-05
215 and 2019-03-30, with maximal velocities reaching 4 m/day. The relatively long 3-month baseline used here,
216 compared to the 12-day baselines in the other maps, demonstrates the possible issue when using feature
217 tracking methods at locations where large and rapid deformation is occurring. The largest deformation
218 events on Negribreen during this time are occurring near the front of the glacier system which may explain
219 why this velocity pattern differs from the others in this series around the front 5 km of the glacier.

220 Figure 5(b) provides mean velocity estimates between 2019-08-11 to 2019-08-23, corresponding to the
221 time of the August 2019 field campaign of (Herzfeld and others, 2022). Maximal surge speeds were near 6
222 m/day. Typically, by August, maximal surge speeds begin to slow significantly from their July maximum.

223 Figure 5(c) provides mean velocities between 2020-07-10 and 2020-07-22 when the glacier system is
224 moving its fastest for the year due to an abundance of meltwater that lubricates the glacier base. Maximal
225 velocities in July 2020 reached 10 m/day, similar to those in July 2019.

226 Finally, Figure 5(d) gives mean velocities between 2020-12-19 and 2020-12-31 near the end of our analysis
227 period. This map provides typical velocities during winter time in Negribreen in 2019 and 2020 with
228 maximal velocities around 4 m/day.

229 3. METHODS

230 3.1. DDA-ice: High Resolution Surface Heights from ICESat-2 Data

231 We applied the DDA-ice algorithm to the raw photon data found in ATL03 to identify the ice-surface
232 signal at sensor resolution, which is then interpolated at 5 m (or less) resolution to attain a final ice-surface
233 height estimate that is used for further analysis. The full mathematical description of the DDA-ice is found
234 in Herzfeld and others (2017) and Herzfeld and others (2021).

235 The central idea of the DDA-ice is to calculate the “density” of returned photons as an additional
236 dimension for identifying signals in the photon cloud. Density is calculated for each photon using a radial
237 basis function that weights neighboring photons using an 2D anisotropic Gaussian kernel biased in the
238 horizontal direction. An auto-adaptive thresholding scheme identifies signal photons by finding the densest
239 photons, which vary in magnitude along-track due to different reflectance properties, background noise and
240 time-of-day. Finally, the DDA-ice uses a ground follower to provide a surface estimate by interpolating the
241 signal photons, weighted by density, at a specified resolution. The surface resolution is increased when the
242 algorithm suspects high surface roughness, such as crevasses, so that these features are correctly traced.

243 The DDA-ice uses algorithm-specific parameters to best identify the type of surface under investigation.
244 Three important parameters that control the shape of the weighting kernel include the standard deviation
245 of the Gaussian distribution (σ , s), the amount of standard deviations used for weighting (cutoff, u)
246 and the anisotropy factor (a) that specifies the ellipticity of the kernel with positive values giving a more
247 horizontally-stretched shape. There are two main parameters that control the thresholding which include
248 the quantile (q) and the offset factor (k). The interpolated surface estimate given by the ground follower

Fig. 5. Negribreen velocity maps from 2019-2020. Maps are derived from Sentinel-1 SAR data. (a) Mean surface velocities between 2019-01-05 to 2019-03-30 (m/day). Over a longer ~ 3 month baseline, velocity information can become lost or skewed in areas of high deformation as seen near the terminus. (b) Mean surface velocities between 2019-08-11 to 2019-08-23 (m/day). This baseline spans the 2019 airborne campaigns in August 2019. (c) Mean surface velocities between 2020-07-10 to 2020-07-22 (m/day) with peak surge speeds exceeding 8 m/day. July typically sees the fastest ice-surface speeds in Negribreen. (d) Mean surface velocities between 2020-12-19 to 2020-12-31 (m/day) at the end of the study period in December 2020 which shows typical velocities during the winter months of 2019 and 2020.

249 has a resolution, R , and provides increased resolution around rough surfaces by a factor of r . The increased
 250 resolution is triggered by the roughness parameter, S , that specifies a standard deviation limit for the

251 vertical distribution of thresholded signal photons. Finally, the estimated depth of crevasses is controlled
252 by the crevasse-quantile parameter, Q . The specific parameter values we use in this analysis of Negribreen
253 are given in Table 1.

254 **3.2. ICESat-2/DDA-ice Data Processing**

255 We ran the DDA-ice on all ICESat-2 ATL03 data over Negribreen from January 2019 through 2020 using
256 the parameters from Table 1, which are close to the “default” parameters given in Herzfeld and others
257 (2021). The same parameter values were used for both the strong and the weak beams. We began by
258 processing all the strong beam data for a given cycle, which consists of three beams per pass with 9 passes
259 (individual RGTs) per cycle. After each run we manually filtered out all the cloudy data by looking at the
260 DDA-ice results so as to be sure that we retain only ice-surface signals.

261 For each beam pass we calculated the along-track “ice-signal fraction” as an indicator of the cloudiness
262 of each measurement pass over the NGS (Column 2 in Table 2). The ice-surface fraction takes the length
263 along-track for which a valid ice-surface height was estimated and divides it by the total along-track survey
264 length. The total along-track survey length (in meters) for each beam pass over the NGS is given in Column
265 3 of Table 2).

symbol	meaning	value
s	standard deviation	3
u	cutoff	1
a	anisotropy	5
q	threshold quantile	0.75
k	threshold bias offset	0
l	slab thickness (m)	30
R	resolution of ground follower (m)	5
r	factor to reduce the R parameter	5
Q	crevasse depth quantile	0.5
S	standard deviation threshold of thresholded signal to trigger small step size in ground follower (m)	1.75

Table 1. DDA-ice parameters for Negribreen runs in this analysis. The same parameters were used for both the strong and weak beams. Ground-follower resolution when ice surface is rough: With $R = 5$ and $r = 5$, then the crevasse-follower resolution is 1 m.

Table 3. Coverage statistics of each RGT and beam over the NGS for 2019-2020 (part 2). This table is a summary of the dat sheet negri_data.2019_2020.xlsx.

266 Next, we processed all the weak-beam data for which the associated strong-beam pair yielded a non-zero
267 ice-signal fraction. Typically, the weak-beam provided a non-zero ice-surface fraction when the associated
268 strong-beam gave an ice-signal fraction greater than 0.9.

269 3.3. Surface Height Change Determination

270 We analyze ice-surface height change across each of the 54 ICESat-2 ground tracks across Negribreen in
271 2019 and 2020 in order to estimate mass transfer occurring during the surge evolution. At the resolution
272 of the DDA-ice interpolated ground estimate (1-5m) however, high-resolution morphology, particularly
273 crevasses, complicate the bulk height change estimate. For example, young surge crevasses forming and
274 evolving in upper Negribreen (Figure 4(b)), which can reach depths of 30 m, act to underestimate the
275 mean surface height of the glacier surface, especially when ground follower resolution is refined over the
276 crevasses. That is, the cross-sectional area of the crevasse voids at the surface is small compared to the
277 total cross-sectional area across the width of the glacier. Height change analysis is further complicated if
278 the geophysical signal we are tracking corresponds to crevasse deepening of crevasses advection. Therefore,
279 for height-change estimates in the case of young surge crevasses in upper Negribreen, we estimate surface
280 height of the glacier surface by using the 90th percentile height for every 30 m along-track bin.

281 Crevasses in lower Negribreen are more complex and have undergone several deformational processes at
282 this point in the surge. While originally they may have resembled the young crevasses in upper Negribreen,
283 large-scale dynamics near the front of the glacier have transformed these mature crevasses to appear
284 markedly different from those in Upper Negribreen as seen in Figure 3(c). Here, the cross-sectional area of
285 crevasse voids is significantly large compared to the total cross-sectional area. We therefore calculate surface
286 heights for height-change analysis in this region by taking the 50th percentile surface height for every 30 m
287 along-track bin. This gives the average surface height within the 30 m bin and smooths out processes that
288 change individual crevasse characteristics that may complicate surface height change determination.

289 3.4. Roughness and Crevasse Characteristics

290 From ICESat-2/DDA-ice surface heights, vario functions are calculated to derive surface roughness values,
291 which are characteristic of the spatial structure of the ice surface (Herzfeld, 2008; Herzfeld and others, 2021).
292 Every 200 m along-track, we calculate discrete first-order vario function vectors, $\mathbf{v}^k = [v_1, \dots, v_j, \dots, v_N]$,
293 within 400 m windows centered at location x_k , which act on n pairs of height estimates, $z(x_i)$ and $z(x_i + h)$
294 separated by some lag distance h grouped in bins defined by the vector \mathbf{h} , whose bounds are indexed by j :

$$v_j^k = \frac{1}{2n} \sum_{i=1}^n (z(x_i) - z(x_i + h))^2 \quad (1)$$

295 where x_i is the along-track location of a height estimate (z) and h is the separation, or lag, distance between
 296 pairs of points with $h_{j-1} < h \leq h_j$, for $j = 1, \dots, N$, with $h_0 = 0$. We use $N = 10$ discrete lag distance bins
 297 of length 40 meters to characterize the surface at a given point x_k , implying $\mathbf{h} = [0, 40, 80, \dots, 400]$.

298 In cases where there are underlying regional trends in the data, such as a glacier's surface slope, it is
 299 more useful to use the residual variogram to quantify roughness (Herzfeld, 2008). Using the mean value m
 300 at a center point x_k , given by

$$m_j^k = \frac{1}{n} \sum_{i=1}^n (z(x_i) - z(x_i + h)) \quad (2)$$

301 the residual variogram V for a reference center point x_k is defined as

$$V_j^k = v_j^k - \frac{1}{2}m_j^k \quad (3)$$

302 where lag distance bins $h_{j-1} < h \leq h_j$, for $j = 1, \dots, N$ are used in both equations 2 and 3.

303 We derive an estimate of surface roughness at point x_k , ζ_k , by taking the maximum of \mathbf{V}^k (i.e. the infinity
 304 norm):

$$\zeta(x_k) = |\mathbf{V}^k|_\infty = \max(\mathbf{V}^k) \quad (4)$$

305 The parameter ζ is equivalent to the 1D *res_pond* parameter in Herzfeld (2008), though in the current
 306 analysis we refer to this quantity simply as roughness (of the glacier surface). This parameter is also
 307 derived using 2D (residual) vario functions applied to satellite imagery of a surging Bering Glacier, Alaska,
 308 in Trantow and Herzfeld (2018).

309 Additional crevasse and crevasse field characteristics, i.e. crevasse spacing and depth, are calculated from
 310 the DDA-ice height outputs for selected ICESat-2 tracks. Crevasse spacing and depth are determined
 311 using a simple deterministic algorithm Herzfeld and others (2013b, 2021, 2022), which identifies individual
 312 crevasses when the so called *jump_height* between crevasse top and crevasse bottom exceeds 2 meters.

313 3.5. Roughness Change Determination

314 We calculate mean rates of roughness change in 2019-2020 using the roughness measure, ζ (or *respond*),
315 derived in Equation 4. While we are interested in the year-to-year dynamical component of roughness
316 change, it is important to consider its significant seasonal component. During the winter months of snow
317 accumulation, approximately October through April, crevasses of moderate and narrow widths can become
318 covered, or bridged, by snow. These snow-covered crevasses can persist throughout the summer in locations
319 of low deformation as seen in Figure 4(a). In this case, only the widest crevasses will be detected by the
320 DDA-ice, which finds the primary signal. The DDA-bifurcate-seaice algorithm (Herzfeld and others, 2023)
321 is able to detect secondary signals such as those beneath the water surface, but is not employed in this
322 analysis as it is not yet reliably adapted to land-ice applications. Because many crevasses are bridged
323 by snow in winter, analysis of roughness change is derived using data from summer months only when
324 snow-bridges are the least prevalent (roughly May through October). During peak melt season in July
325 and August however, crevasses exist that are filled with water at locations where the surge deformation
326 has destroyed normal englacial drainage paths that route water from the glacier surface to the base (see
327 image in Figure 4(b)) (Kamb and others, 1985; Harrison and Post, 2003). Water-filled crevasses are present
328 throughout the glacier system but affect only a small number of the total crevasses (Herzfeld and others,
329 2022), and therefore should not significantly affect the overall roughness estimates in this analysis.

330 4. RESULTS

331 4.1. Surface Height and Surface Height Change

332 4.1.1. Surface Heights and Data Coverage for each ICESat-2 Cycle

333 Along-track ice-surface height estimates yielded by the DDA-ice ground follower at 1-5 m resolution, as
334 determined by the algorithmic parameters in Table 1, are given for the four cycles in 2019 (Figure 6) and
335 the four cycles in 2020 (Figure 7). Heights in the NGS range from ~ 0 m (sea-surface height) at the terminus
336 to over 800 m in the upper tributary glaciers.

337 The most sparse coverage of the glacier system occurs during the late-summer/autumn months,
338 particularly in the lower part of the glacier system, when low-level mixed-phase clouds (MPCs) have their
339 highest occurrence (Shupe and others, 2006; de Boer and others, 2009; Shupe and others, 2011; Gierens
340 and others, 2020) (see Figure 3(a)). During all but a couple cycles, Akademikarbreen is more densely

341 covered than Ordonnansbreen likely due to the local orography which strongly influences the occurrence
 342 and characteristics of MPCs (Gierens and others, 2020).

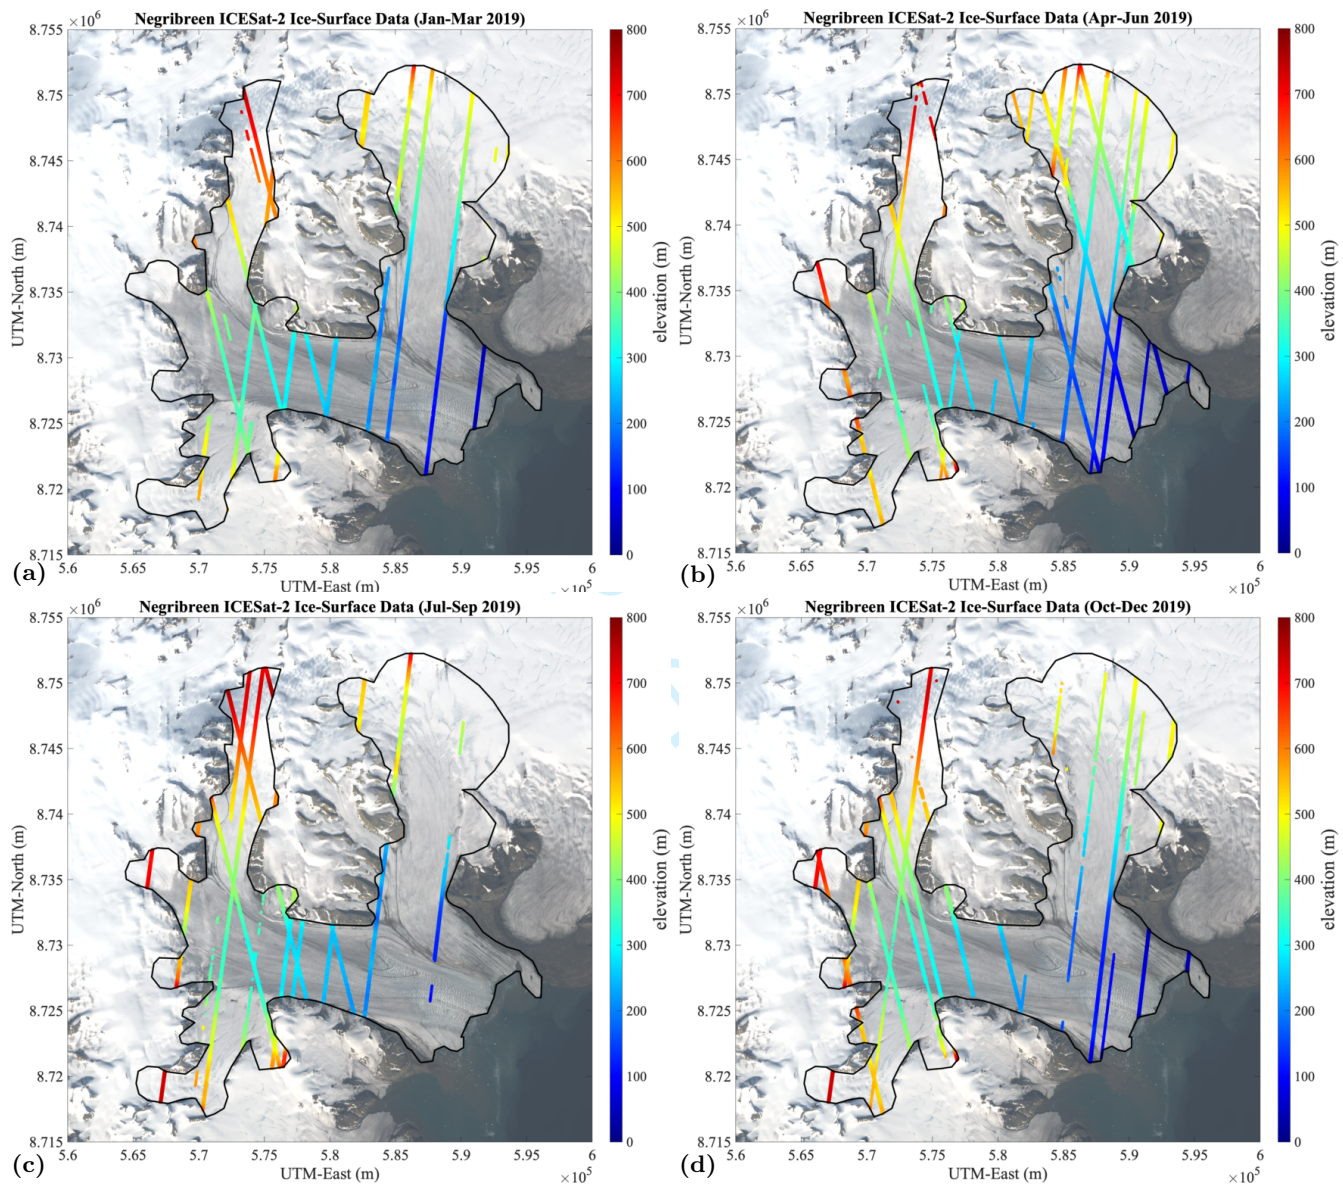

Fig. 6. 2019 Negribreen ice-surface height data from the DDA-ice for single ICESat-2 cycles (91 days).

(a) January-March 2019, (b) April-June 2019, (c) July-September 2019, (d) October-December 2019.

343 4.1.2. Surface Height Rate of Change (2019-2020)

344 Figure 8 gives the average surface height rate of change from 2019 to 2020 following the processes outlined
 345 in Section 3.3. While this calculation provides mean height changes in meters per year, it is important to
 346 note that the majority of the change occurs in the summer months, with very little height change between
 347 January and April. This is seen more clearly in the times series plots of Section 4.3.

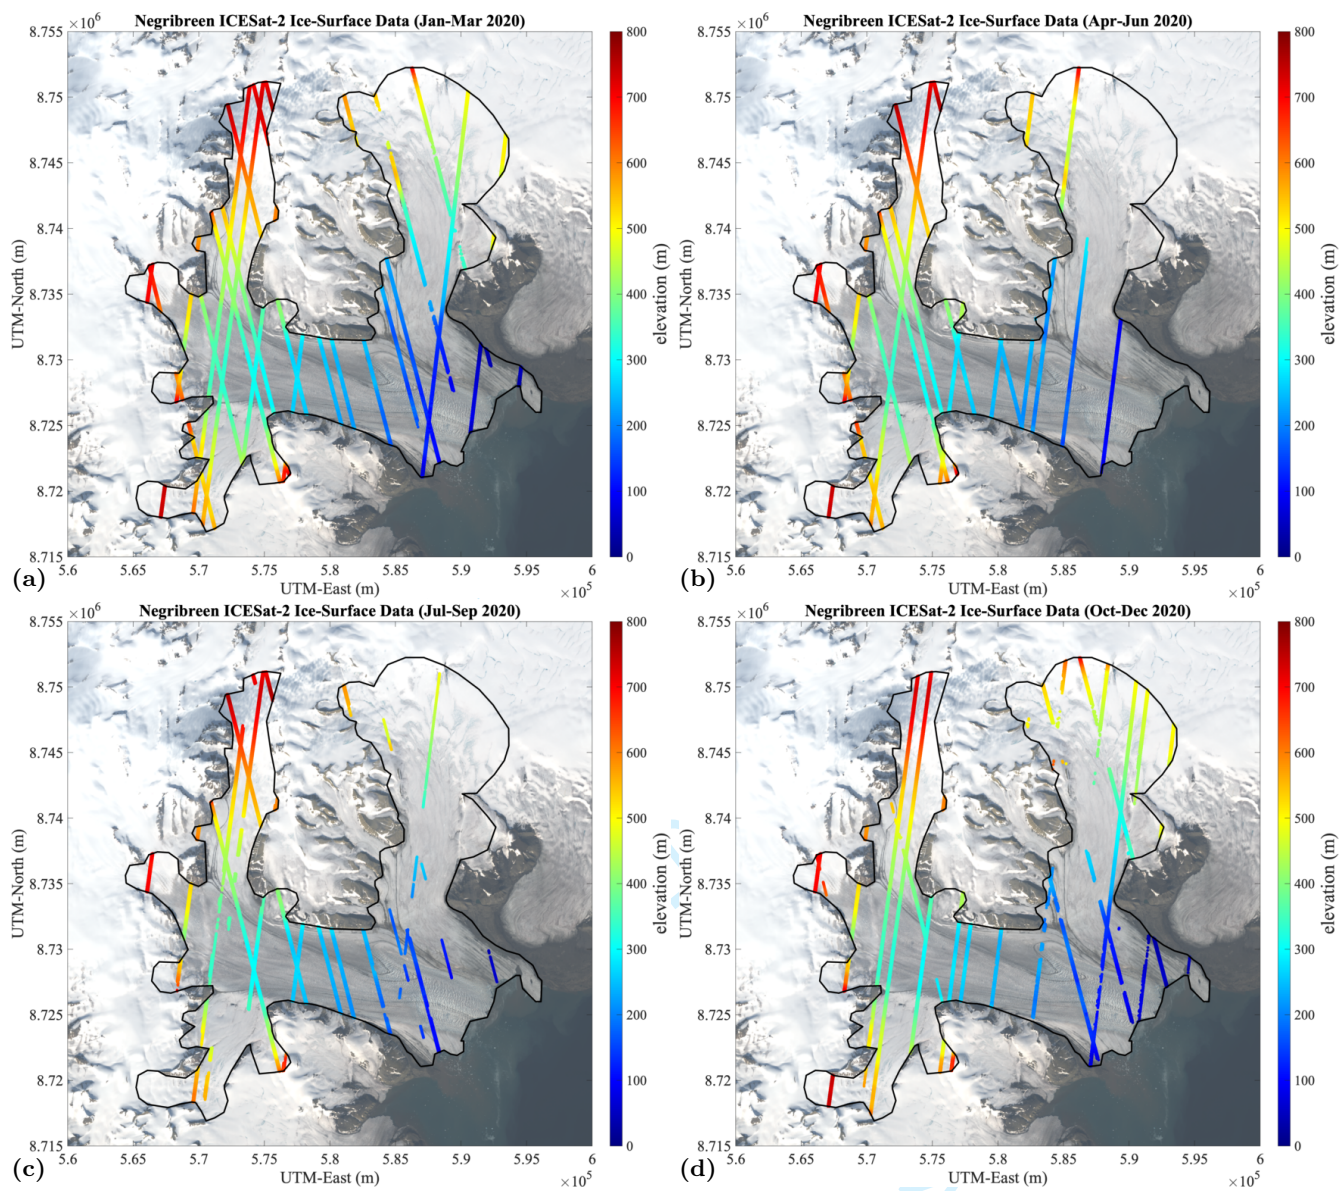

Fig. 7. 2020 Negribreen ice-surface height data from the DDA-ice for single ICESat-2 cycles (91 days).

(a) January-March 2020, (b) April-June 2020, (c) July-September 2020, (d) October-December 2020.

348 Figure 8 shows general thinning in the upper glacier above 5.85×10^5 m UTM-East and general thickening
 349 in the lower glacier below, implying a mass transfer from the upper glacier to the lower glacier. Surface
 350 heights grew between 2019 to 2020 in the front $\sim 1/3$ of the glacier at a rate reaching 30 m/year near
 351 Negribreen's terminus. A chaotic pattern of tightly spaced surface lowering and surface gains exceeding \pm
 352 30 m/yr near the center-front of the glacier reflects the generation and advection of massive and complex
 353 crevasses (see image in Figure 3(c)).

354 Surface lowering occurs in the upper $\sim 2/3$ of Negribreen, while surface heights remain mostly constant
 355 on tributary glaciers such as Akademikarbreen and Rembebreen, which is seen clearly at the crossing of the

356 medial moraines in Figure 8. Aside from a slight lowering near its terminus, Ordonnansbreen also saw little
 357 changes in surface height from 2019 to 2020 despite the significant height changes occurring just across the
 358 medial moraine on the surging Negribreen.

359 There is, however, a clear surface lowering of around 8 m/yr on Transparentbreen, which connects
 360 Negribreen to the Filchnerfonna accumulation zone above the NGS. Thus, the surge of Negribreen is
 361 affecting additional parts of the glacier system, expanding beyond the main glacier, across Transparentbreen
 362 and into the large catchment area above the glacier (Filchnerfonna). Transparentbreen appears to be the
 363 only tributary glacier in the NGS experiencing significant height-change during the surge expansion from
 364 2019 to 2020.

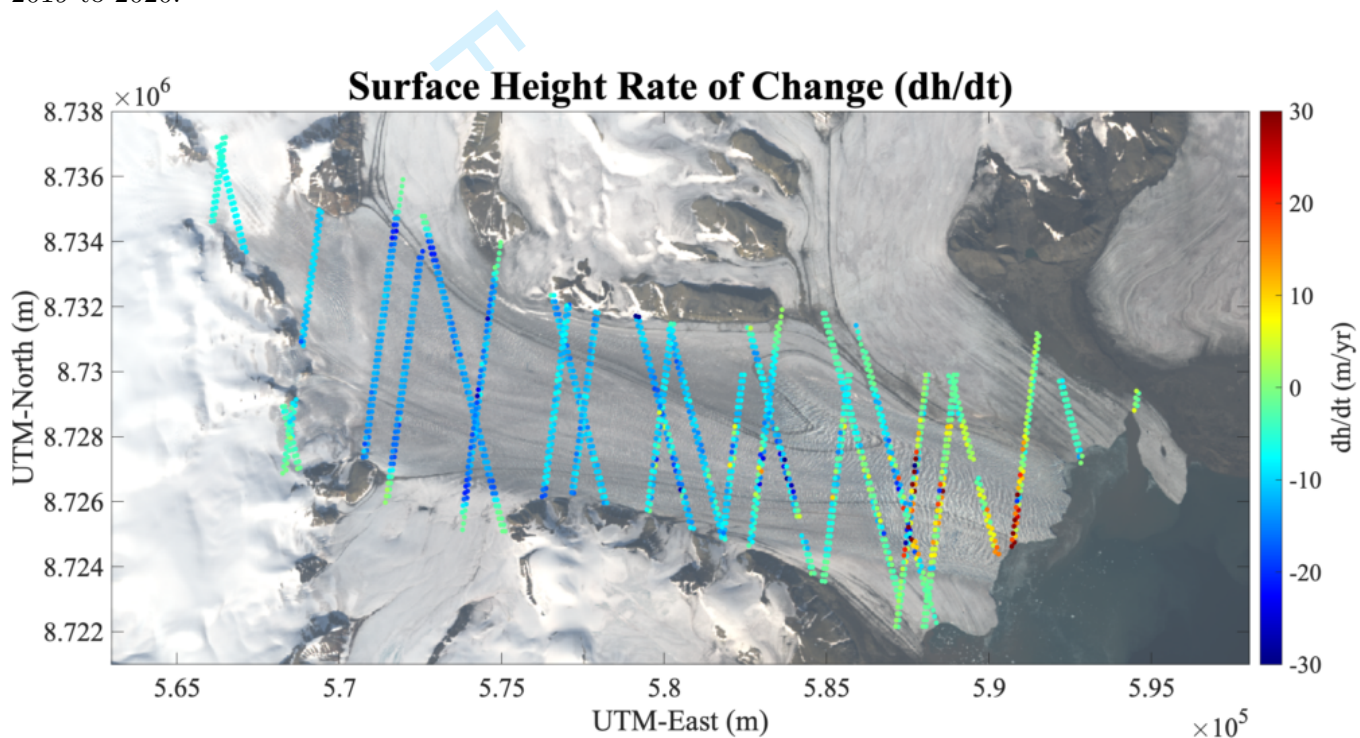

Fig. 8. Rates of change of glacier surface height during the 2019-2020 part of the recent Negribreen surge. Surface height change rate in meters per year.

365 4.2. Surface Roughness and Roughness Change

366 Crevassed regions are indicated by high surface roughness (Herzfeld, 2008; Herzfeld and others, 2014;
 367 Trantow and Herzfeld, 2018; Herzfeld and others, 2021, 2022). Negribreen's ice-surface roughness, given by
 368 ζ in Equation 4 (*respond*), for the four ICESat-2 cycles of 2019 and 2020 is shown in Figures 9 and 10
 369 respectively. The medial moraines provide a clear boundary between the rough and surging Negribreen and
 370 the relatively smooth surfaces of the non-surging tributary glaciers. In general, roughness is larger further

371 downglacier as the surging ice experiences more deformation events moving through the glacier system
372 with the strongest events experienced near the glacier front where surge velocities are largest (Figure 5).

373 Figure 11 gives the mean rate of change of dynamically-induced roughness over the 2019-2020 period
374 of the NGS surge following the approach discussed in Section 3.5. Negribreen began surging in 2016 near
375 the glacier front and has expanded upglacier as the surge matures (Haga and others, 2020; Herzfeld and
376 others, 2022). We see that for the most part, surface roughness has decreased in the lower glacier reflecting
377 reduced surge activity at that location. There are locations in the lower glacier however, that have seen
378 increased roughness indicating the continued occurrence of strong, but isolated, surge deformation events.

379 In contrast, large portions of the upper glacier experienced increased roughness over the study time
380 interval (e.g., yellow regions in Figure 11), which reflects the expansion of the surge up-glacier in Negribreen.
381 Large increases in surface roughness also occurred in the ice falls between the Filchnerfonna and Negribreen,
382 which illustrates further expansion of surge effects beyond Negribreen and into the accumulation zone above
383 the glacier.

384 4.3. Time Series of ICESat-2 Surface Height Profiles

385 In this section, we analyze time series of selected ICESat-2 profiles that allow derivation of glaciological
386 changes associated with the surge of the NGS in 2019-2020. We present a subset ICESat-2 profiles, identified
387 by their associated RGT and beam, based on the glaciological insight that their result provided. The full
388 collection of ICESat-2 time series for each of the 54 ICESat-2 profiles can be found in the supplementary
389 material (negri.change.suppl.pdf).

390 4.3.1. Detection of New Surge Crevasses and Changes in Existing Crevasse Fields

391 ICESat-2 data analyzed with the DDA-ice facilitate identification of crevasses (Herzfeld and others, 2017,
392 2021, 2022). Here we utilize this crevasse detection capability to analyze and map the progression of the
393 surge through the NGS in 2019-2020.

394 All crevasse fields observed and analyzed here evolved morphologically through expansion or contraction,
395 advection down-glacier, formation of a snow-bridge and/or filling with water. An example of crevasse
396 expansion is given by the occurrence of new crevasse fields formed in upper Negribreen along RGT 594 gt11
397 as seen in Figure 12(b) between 8.727 and 8.728×10^5 UTM-North where a smooth, uncreavssed ice-surface
398 is reported in early 2019 (orange and yellow lines), and at the same location new crevasses have opened
399 by November 2019 (green line). This particular finding indicates that additional crevasse fields formed
400 in the southern part of upper Negribreen in late 2019, south of an existing larger crevasse field closer

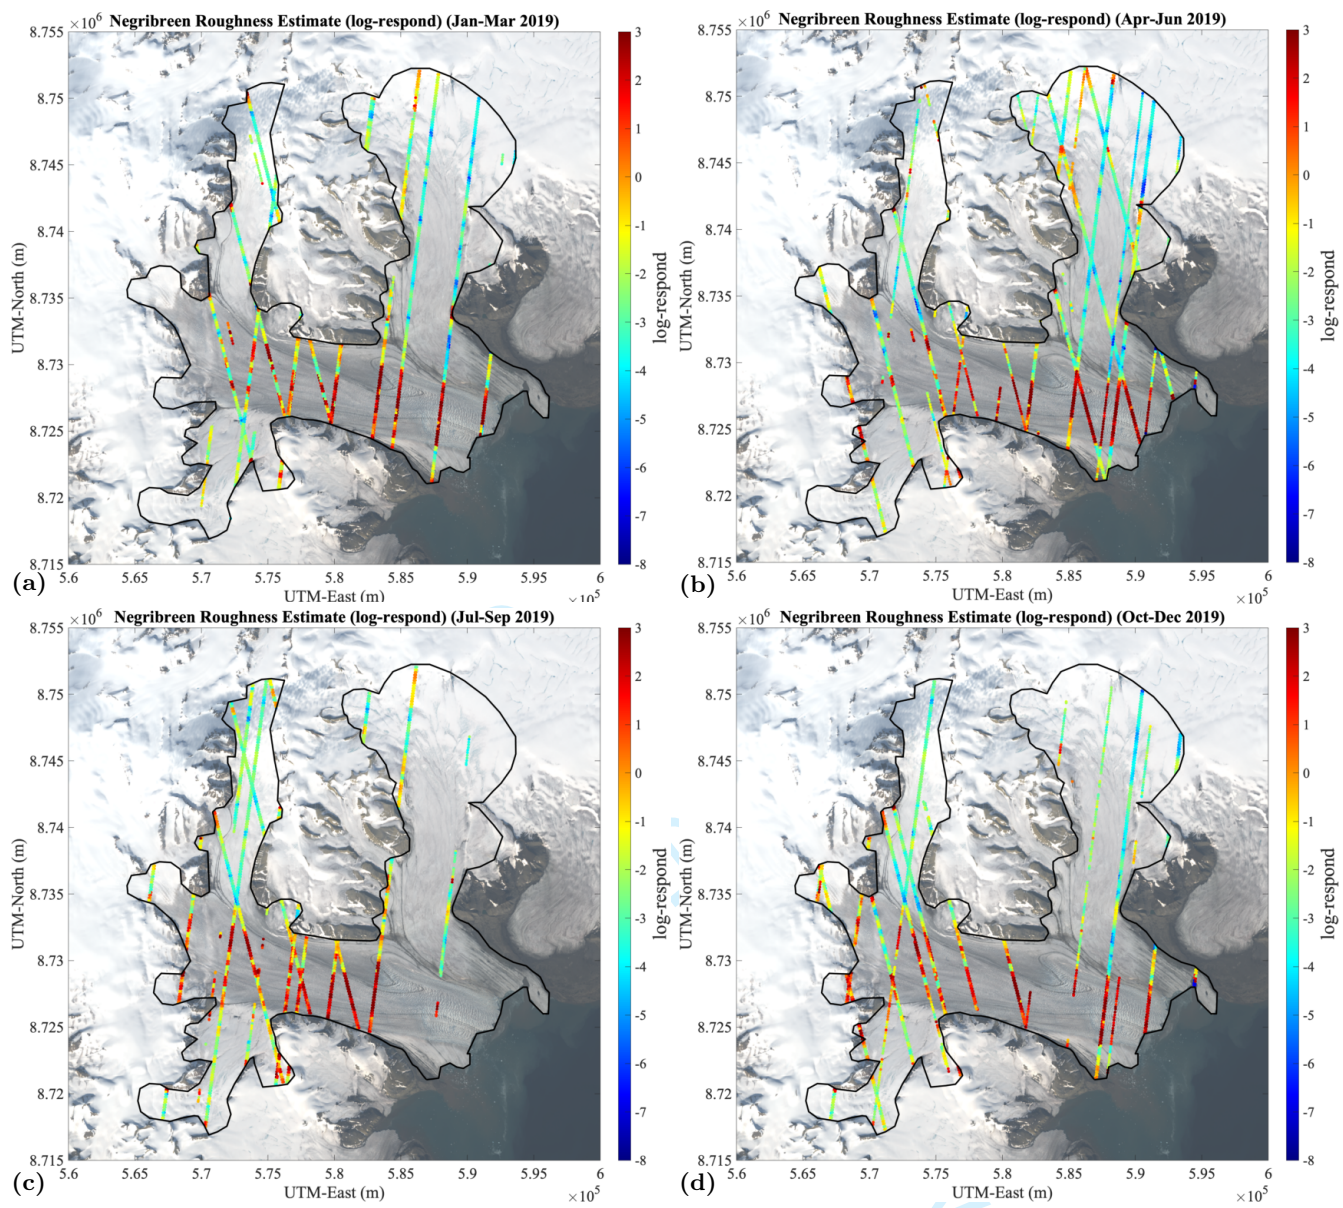

Fig. 9. 2019 Negribreen roughness data per cycle as given by the logarithm of the *logpond* parameter.

(a) January-March 2019, (b) April-June 2019, (c) July-September 2019, (d) October-December 2019.

401 to the boundary with Akademikarbreen. The latter crevasse field was overflowed during the airborne field
 402 campaigns in 2018 and 2019 (Herzfeld and others, 2021), and RGT 594 gt11 as a whole was utilized in the
 403 validation campaign of Herzfeld and others (2022). Another example of the detection of crevasse expansion
 404 is found along RGT 594 gt21 in Figure 12(d) near 8.726×10^5 m UTM-North where large crevasses formed
 405 along Negribreen's southern margin between February and April 2020.

406 Further evidence of the expansion in upper Negribreen is given by the time series of RGT 450 in Figure
 407 13(a)-(d). Large crevasses reaching 10 m depths near the southern margin formed in early 2020 similar
 408 to those detected in the nearby RGT 594 data (Figure 12). Note that beam-pair 1 of RGT 450 is also

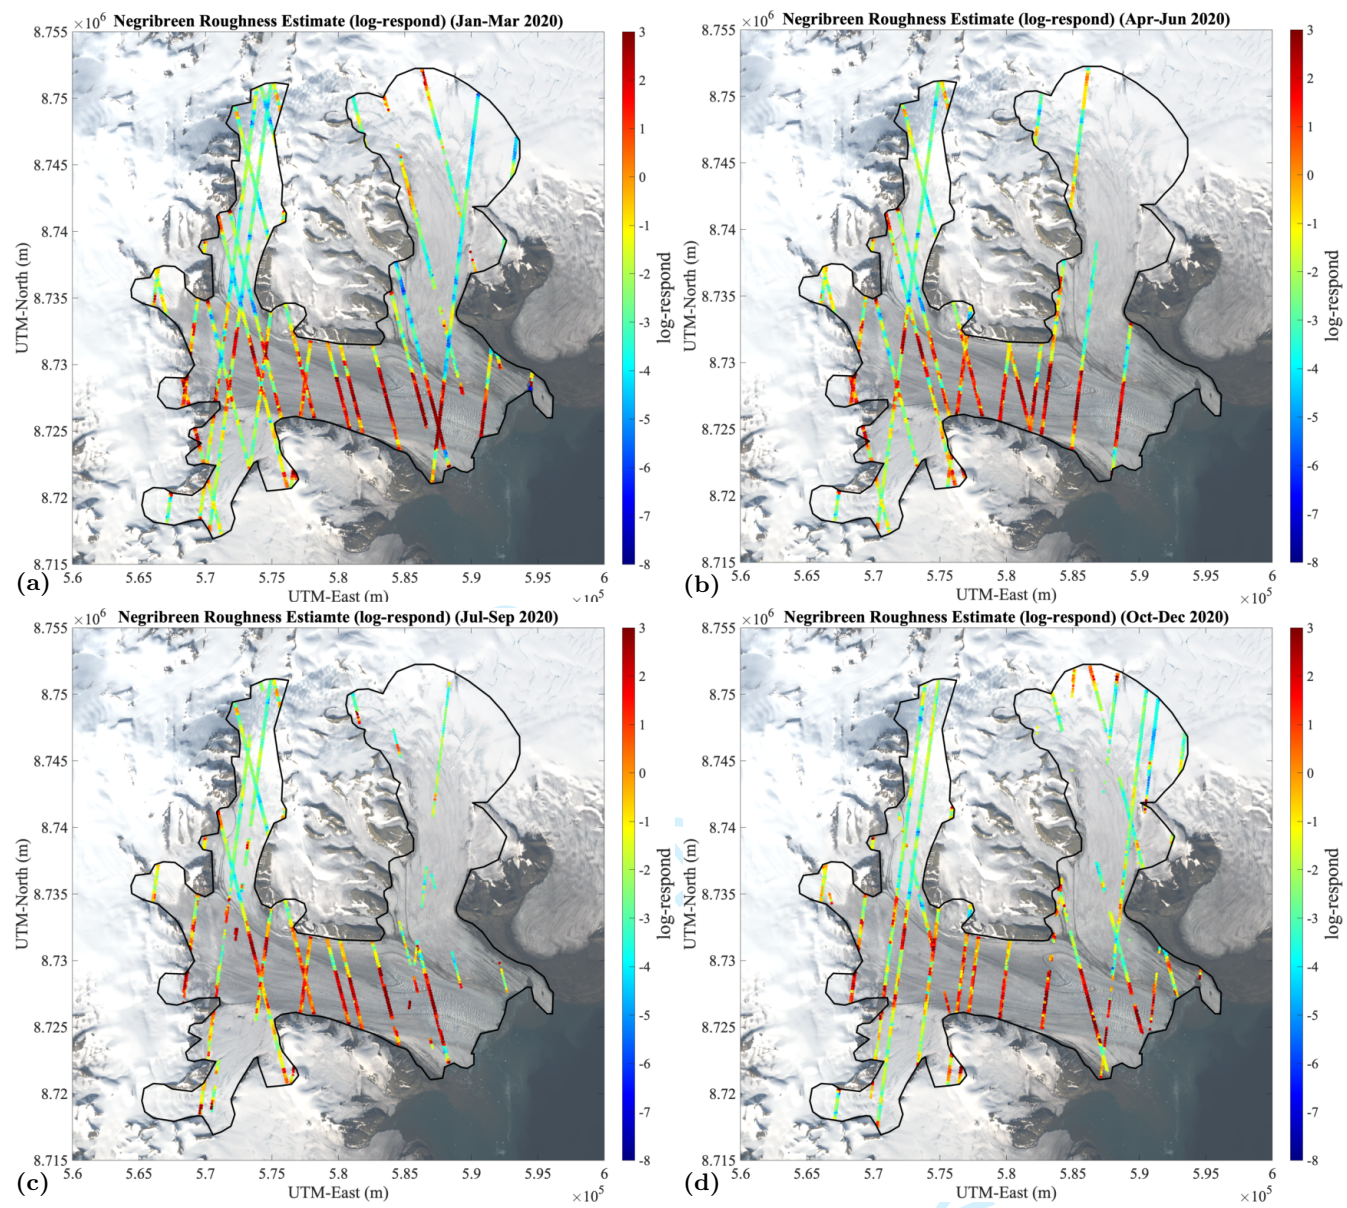

Fig. 10. 2020 Negribreen roughness data per cycle as given by the logarithm of the *logpond* parameter.

(a) January-March 2020, (b) April-June 2020, (c) July-September 2020, (d) October-December 2020.

409 surveyed and analyzed in Herzfeld and others (2022), which shows consistent detection of ~ 10 m deep
 410 crevasses in both the ICESat-2/DDA-ice and the airborne laser altimeter (ULS) data in 2019. In addition,
 411 13(e)-(f), which plots RGT 152 gt3r, shows crevasse expansion across both the northern and southern
 412 margin between early 2019 (orange line) and 2020 (green, blue, brown lines). RGT 152 gt3r also presents
 413 an example of isolated crevassing and crevasse enlargement in the center of upper Negribreen near 8.729
 414 $\times 10^5$ m UTM-North.

415 The apparent disappearance of crevasses from 2019 to 2020, such as those in Figure 12(f) near
 416 8.729×10^5 m UTM-North, may be from crevasse contraction, advection down-glacier without up-glacier

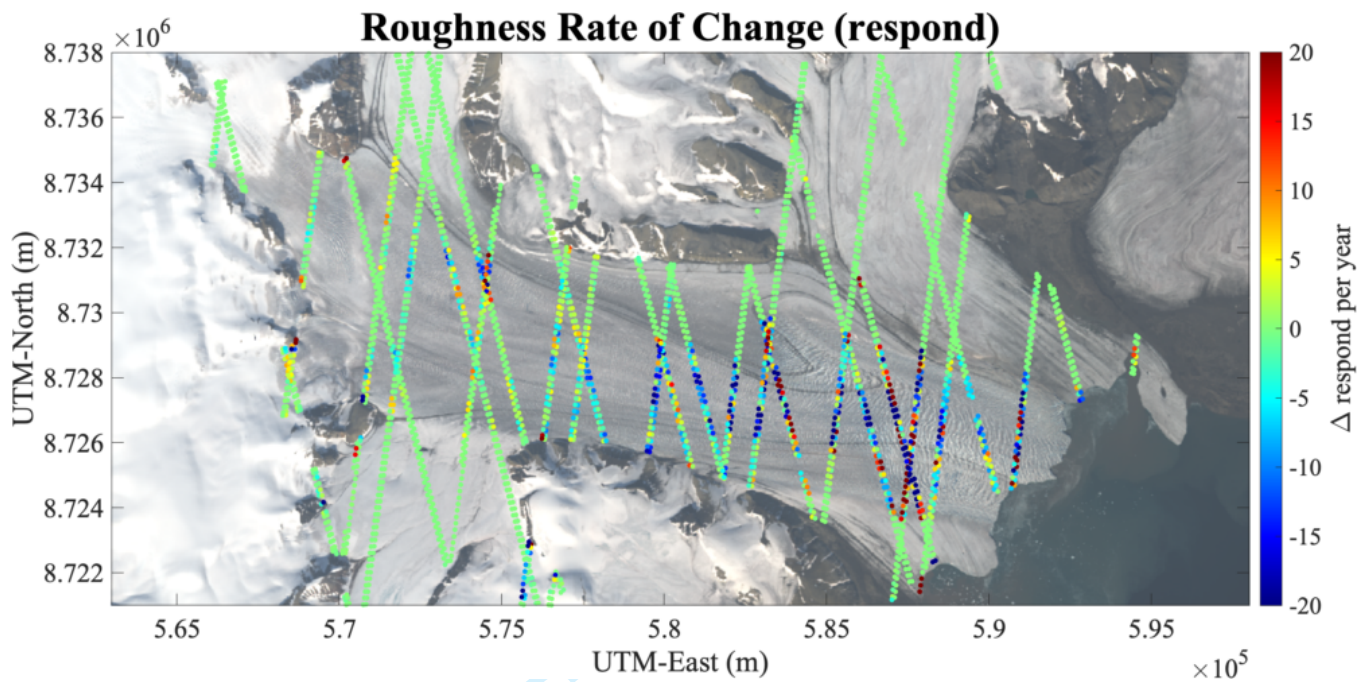

Fig. 11. Rates of change of roughness during the 2019-2020 part of the recent Negribreen surge. Roughness (logpond) change rate in Δ_{pond} per year.

417 replacement of similar crevasses, snow-bridge formation or becoming filled with water. Imagery may be
 418 used to determine the exact process involved. The airborne photograph in Figure 3(a), taken near 8.729
 419 $\times 10^5$ m UTM-North, shows that the crevasses under consideration, i.e. those found in and to the left of
 420 the medial moraine in the image, have become bridged by snow.

421 Returning to RGT 594 gt11, we proceed to investigate changes in the width and depth of crevasses in the
 422 large crevasse field seen in Figure 12(b) between 8.730 and 8.732×10^5 UTM-North. Mean surface height
 423 change (surface lowering) along this 2 km segment was -11.66 m between August 2019 and August 2020.
 424 Mean crevasse spacing increased from 55.45 m to 57.6 m, mean depth decreased from 10.71 m to 9.82 m,
 425 and maximum depth decreased from 16.01 m to 15.82 m. These changes in the crevasse characteristics
 426 are typical of changes in a crevasse fields that formed during earlier years of the surge in 2017 or 2018, as
 427 recorded during our field campaigns. This result is consistent with the plot of Figure 11 that reveals this
 428 region to be the only one in upper Negribreen that saw a decrease in surface roughness from 2019 to 2020.
 429 Over time, crevasses tend to widen a little, become shallower, and the crevasse edges are more rounded, as
 430 erosion progresses (Herzfeld and others, 2013b).

431 In general, we find that the local maximum of crevasse depth increases from up-glacier to down-glacier
 432 regions of Negribreen. From ~ 16 m depth along RGT 594 gt11 in upper Negribreen, maximal depths

433 increase to ~ 22 m near the mid-glacier along RGT gt31 (Figure 12(f)) and exceed 30 m in the lower glacier
 434 near the terminus.

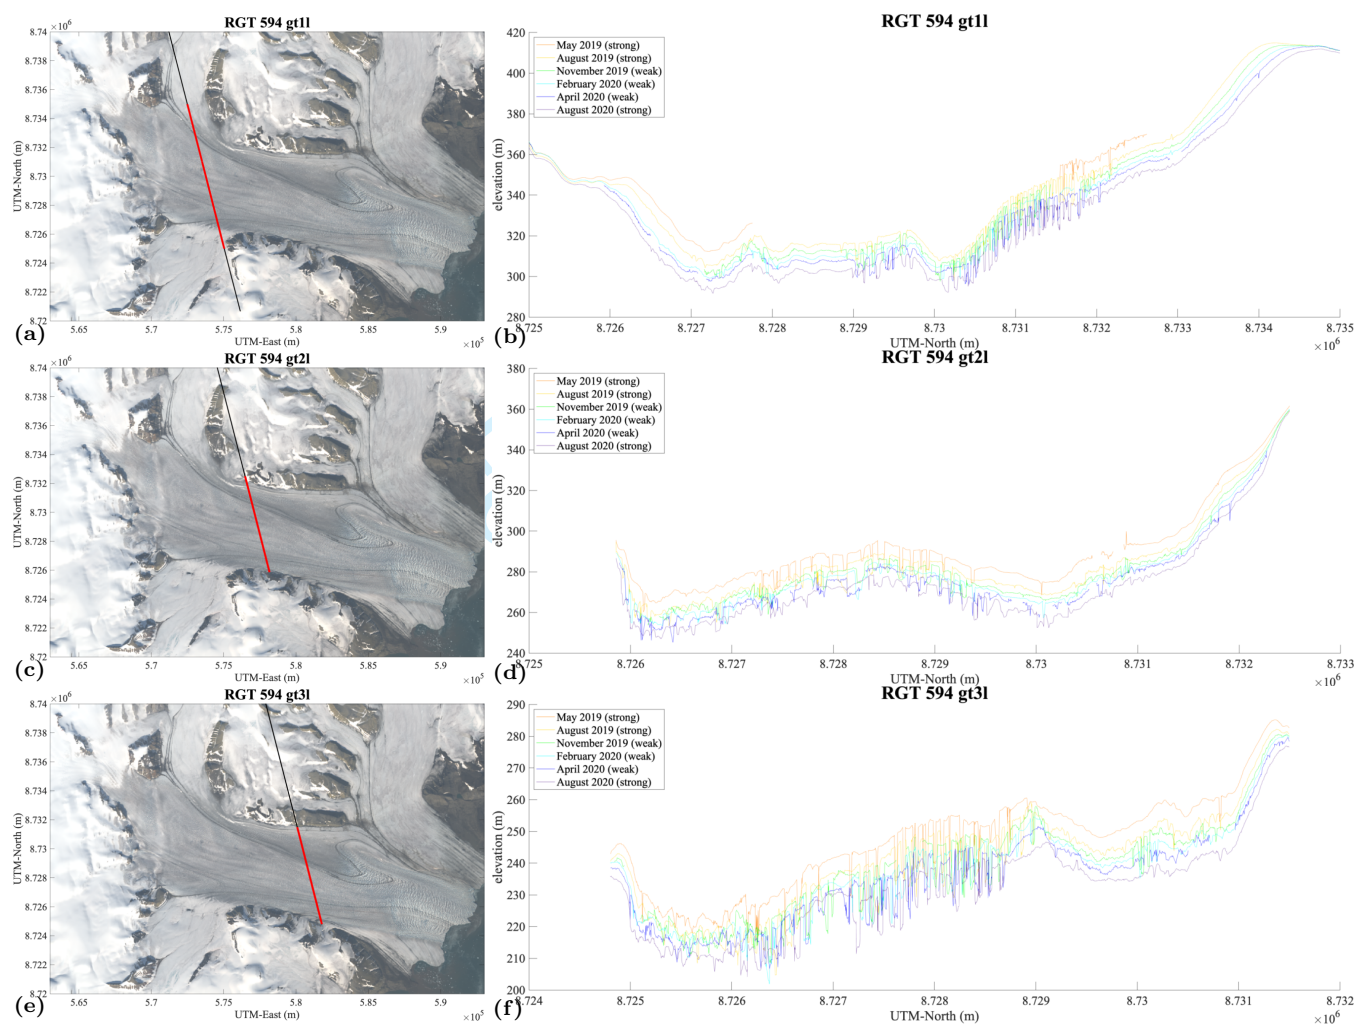

Fig. 12. DDA-ice results for RGT 594 over the Negribreen's major surge-affected area, 2019-2020. (a)-(b) RGT 594 gt11, (c)-(d) RGT 594 gt21, and (e)-(f) RGT 594 gt31.

435 4.3.2. Surge Expansion Along and Across the Shear Margin

436 The Negribreen-Akademikarbreen Medial Moraine (NAMM) is easily identified in airborne and satellite
 437 imagery as the dark dividing line between the surging ice of Negribreen and the non-surging ice to the
 438 north. From its formation point at the Negribreen-Akademikarbreen junction, the NAMM advects down-
 439 glacier, past the Lykkenhøgda hills at mid-glacier and along the Negribreen-Ordonnansbreen border in the
 440 lower glacier, leaving an obvious stripe through Negribreen near its northern margin. The NAMM provides
 441 an example of the folded moraine that can be used to identify a glacier as a surge glacier (Post, 1972;
 442 Lefauconnier and Hagen, 1991). The fold results from a shift in the dynamic equilibrium between a surge
 443 glacier (here, Negribreen) and a neighboring, non-surging glacier (Ordonnansbreen).

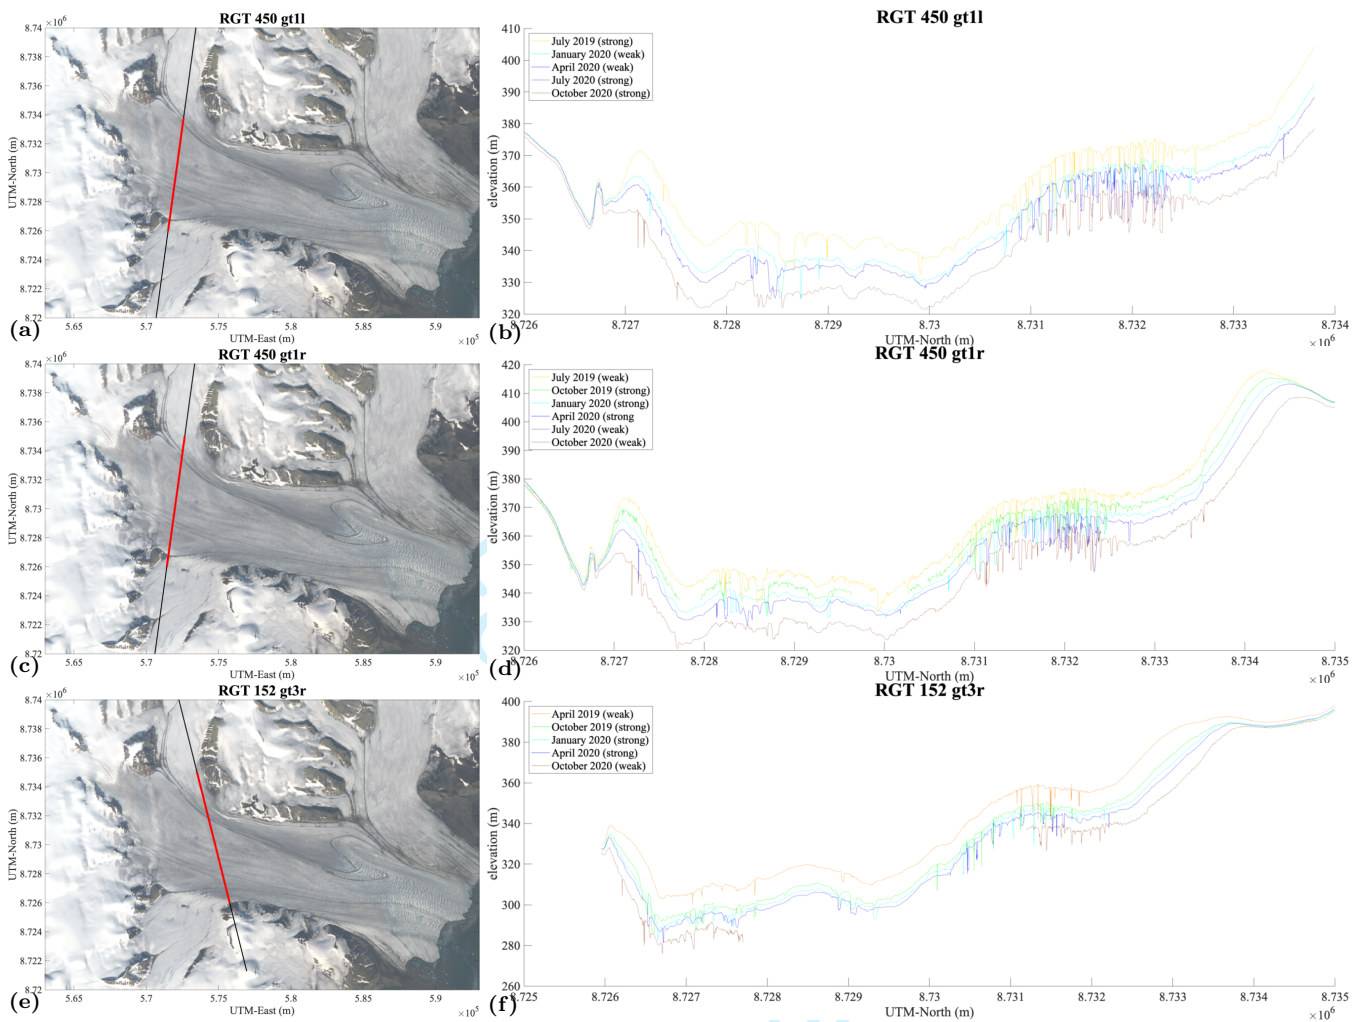

Fig. 13. Further expansion of crevasses in upper Negribreen as given by ICESat-2's RGT 450 and 152, 2019-2020. (a)-(b) RGT 450 gt11, (c)-(d) RGT 450 gt1r and (e)-(f) RGT 152 gt3r.

444 Throughout Negribreen's longitudinal extent, large shear stresses exist around the NAMM due to its
 445 boundary between the surging ice of Negribreen and the non-surging ice of the northern tributary glaciers.
 446 In 2017 and 2018, Herzfeld and others (2022) documented the disintegration of the lower NAMM, i.e., the
 447 Negribreen-Ordonnansbreen shear margin, along which the terminus retreated via processes of rifting and
 448 calving at a pace faster than observed elsewhere in the glacier (visualized as a "retreating bay" at the
 449 terminus). The formation of bays and melange areas occur at former areas of so-called chaotic crevasse
 450 types (Herzfeld and others, 2013a), which are often found at locations with large shear stresses.

451 In the current analysis of surge progression, we detect the development of additional large crevasses in
 452 northern Negribreen in the upper-mid glacier around the NAMM (i.e. up-glacier of the largest "retreating
 453 bay" observed in 2017) in 2020. Figures 14(a)-(d) display a transverse expansion of crevasse (outward
 454 toward the NAMM), recorded in RGT 892 gt11 and gt1r. In August 2019 (yellow lines) deep crevasses

455 (~ 10 m) are measured across the majority of the glacier with a northern extent around 8.729×10^6 m
456 UTM-North. By August 2020 (purple lines), one year later, these large 10 m deep crevasses are seen to
457 expand transversely (northward) approximately 5 km to the extent of 8.7295×10^6 m UTM-North. These
458 new crevasses appear to be wider than the older ones to the south and are an indication of the intensification
459 of the shear margin.

460 In August 2019, before this noted expansion, large amounts of water were observed in the crevasses near
461 the northern NAMM as seen in Figure 4(c). The presence of clear blue meltwater in crevasses is indicative
462 of a local disruption in the englacial drainage system which can occur in when the surge progresses into a
463 region. Once the drainage pathway reestablishes, the water observed in the crevasses suddenly and rapidly
464 drains to the subglacial system causing a rapid acceleration of the local ice via basal sliding through
465 decreased friction between the glacier base and the underlying bedrock (Cuffey and Paterson, 2010). A
466 local surge in the ice, part of the larger surge complex experienced throughout the glacier system since
467 2016, results in large crevasses such as those detected here around the NAMM.

468 In Figure 14(e)-(h), gt2l and gt2r of RGT 1334 show the same transverse (northern) expansion of
469 crevassing across the NAMM at the mid-glacier. The large 10 m deep crevasses expand toward the NAMM
470 beginning at 8.7288×10^6 m UTM-North September 2019 (yellow lines), up to 8.7289×10^6 m UTM-North
471 by June 2020 (blue lines) and to 8.729×10^6 m UTM-North by December 2020 (brown line, visible only in
472 gt2l due to partial cloud cover). Again, these changes are reflected in Figure 11 where increased roughness
473 is observed from 2019 to 2020 at locations near the NAMM in upper Negribreen. Additional evidence
474 of crevasse expansion along and across the NAMM is given in 13(e)-(f) for RGT 152 gt3r which surveys
475 Negribreen just up-glacier of RGT 1334 gt1l/r.

476 Our ICESat-2 results of fresh crevassing in mid and upper Negribreen around the NAMM indicate an
477 expansion of shear margin disintegration up-glacier from a retreating bay at the terminus. Taken together,
478 the NAMM disintegration and the retreating bays at the terminus illustrate the evolution of a shear margin
479 with a very strong velocity gradient along a folded moraine (see velocity maps in Figure 5). This result
480 demonstrates how time series of ICESat-2 data, analyzed with the DDA-ice, can be employed to derive
481 quantitative information about complex surge processes, here, transverse deformation across a medial
482 moraine forming a shear margin with increasingly large stress gradients as the surge evolves. To our
483 knowledge, this is a new capability of satellite-based observation.

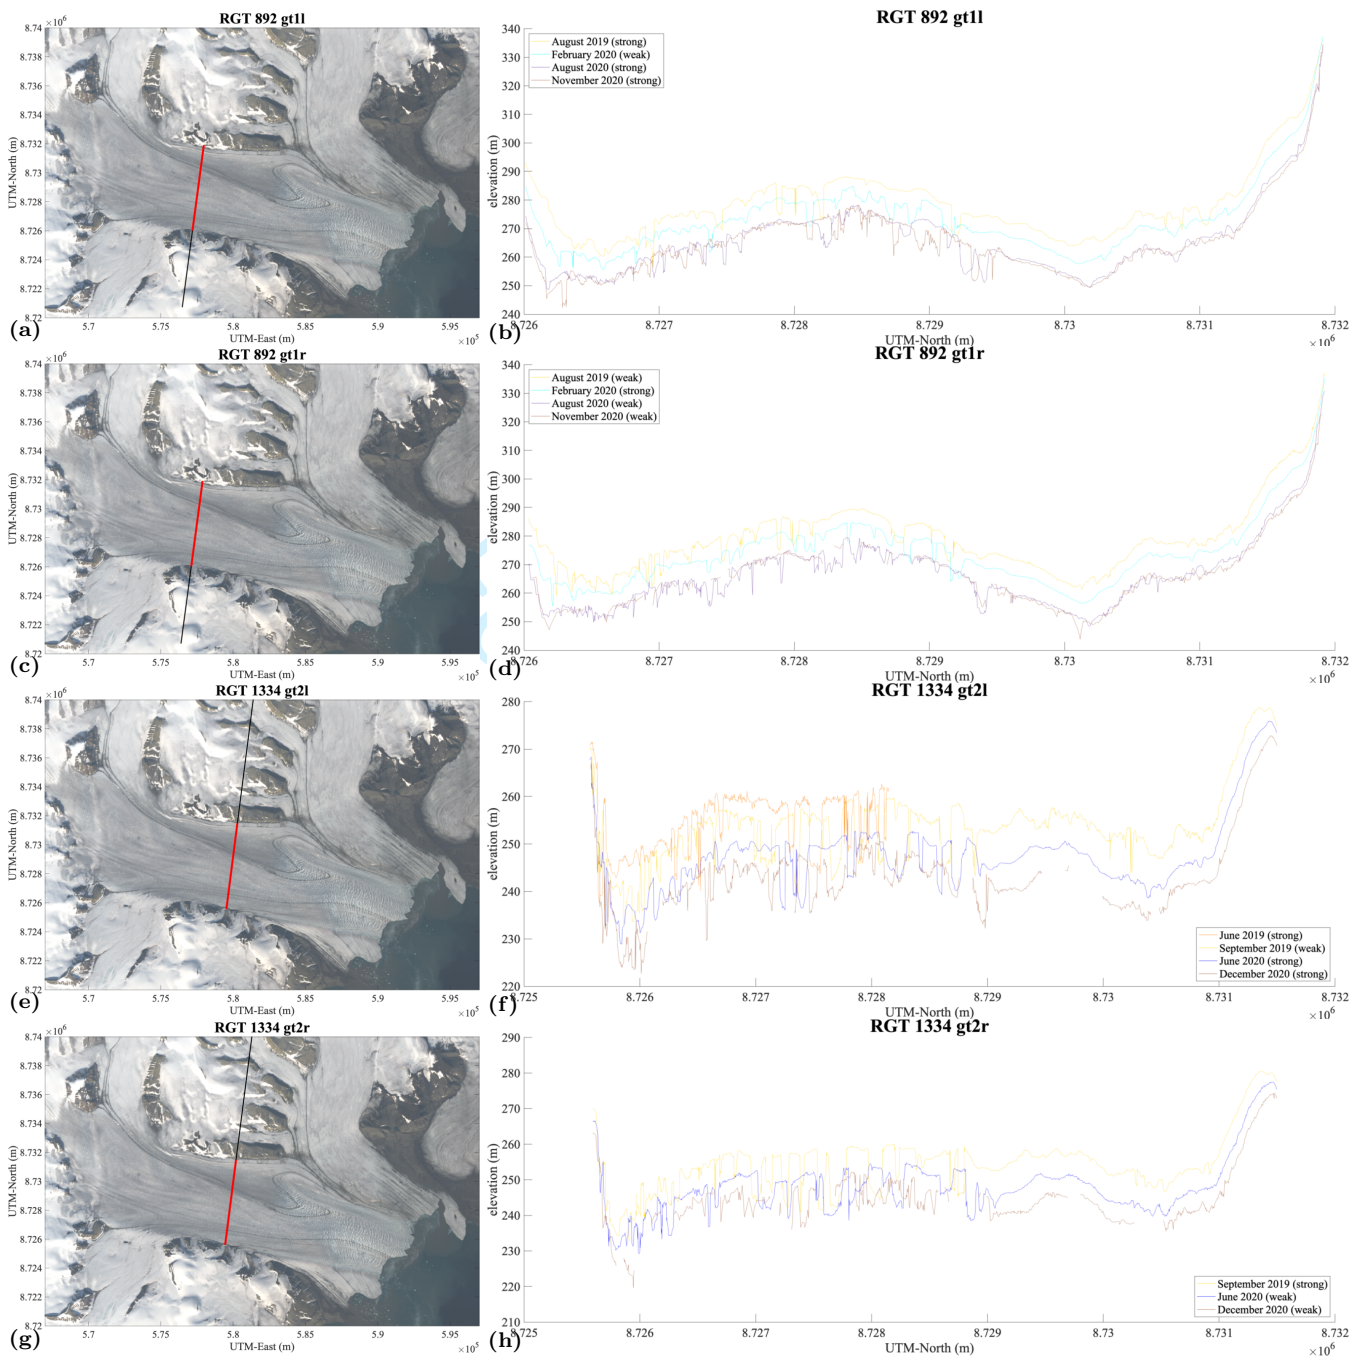

Fig. 14. DDA-ice results near the Negribreen-Akademikarbreen Medial Moraine (NAMM), 2019-2020. (a)-(b) RGT 892 gt1l, (c)-(d) RGT 892 gt1r, (e)-(f) RGT 1334 gt2l, and (g)-(h) RGT 1334 gt2r.

484 4.3.3. Disintegration of the Ordonnansbreen Tooth

485 The Ordonnansbreen tooth, a small area of ice indicated by a black arrow in Figure 1(e), has been detaching
 486 from Ordonnansbreen's north terminus since the surge began in 2016. As noted earlier, Ordonnansbreen
 487 has been moving at quiescent speeds throughout our total observation time (2016-2021)), as seen in the
 488 velocity maps of Figure 5.

489 The detaching tooth, along with the greater disintegration of the ice along the nearby medial moraine
490 (lower NAMM), is visualized in the time series of Landsat-8 RGB imagery from 2018-2021 in Figure 1. In
491 2018 (Fig. 1(b)) the tooth is attached to the northern part of the Ordonnansbreen terminus. The tooth's
492 connection with the terminus shrinks by August 2019 (Fig. 1(c)) and becomes totally disconnected by
493 July 2020 (Fig. 1(d)). Ordonnansbreen's terminus rapidly retreats between July 2020 and August 2021
494 (Fig. 1(e)), greatly increasing the distance between the shore-fast tooth and the calving front. While the
495 Landsat-8 imagery helps visualize this process in two spatial dimensions, only with the ICESat-2 data
496 do we get surface height and rifting-depth information to elucidate the third dimension of this rapidly
497 changing glacial feature.

498 We see the separation of Ordonnansbreen's tooth in the time series of RGT 91 gt3l and gt3r (Figure 15),
499 which both cross the terminus of Ordonnansbreen. The orange line in Figure 15, representing the ice-surface
500 in April 2019, shows continuous ice extending from the shore line at 8.73×10^6 m UTM-North to the calving
501 front near 8.7274×10^6 m UTM-North. By January 2020, a ~ 10 m deep rift developed near 8.7299×10^6 m
502 UTM-North that penetrates all the way to the ocean surface, disconnecting the majority of the tooth from
503 the main glacier (see cyan-colored line in Figure 15). The rift geometry at this location appears to have
504 remained relatively fixed between January 2020 (cyan) and July 2020 (purple, gt3l only) indicating little
505 surge activity during this time. By September 2020 (brown lines), the rift between Ordonnansbreen and the
506 tooth increased significantly from ~ 400 m to over 1.5 km in the direction of the RGT 91 survey line. The
507 September 2020 results in RGT 91 gt3r (Figure 15(d)) in particular, indicate the presence large icebergs
508 and an even greater separation distance nearing 5 km between the tooth and the main glacier. These results
509 indicate that the process of tooth detachment occurs most rapidly during peak glacier velocities in late
510 summer implying that the initial rift likely developed sometime around July or August 2019.

511 Looking at the entirety of the RGT 91 gt3l/r survey lines, we observe an ice-surface lowering of 4-
512 5 m across the Ordonnansbreen terminus during the 15 months between April 2019 and July 2020, i.e.,
513 approximately 20% of its total thickness, indicating rapid height and mass loss. This ice-surface continued
514 to lower by ~ 1 m across the entire width during the 3 months between July and September 2020. Therefore,
515 while the majority of Ordonnansbreen remains in a quiescent state, the Negribreen surge still has a
516 significant effect on the evolution of its neighboring tributary glacier through dramatic surface lowering,
517 rifting and calving at the terminus. The surge effects here, along with the major deformation along its

518 medial moraine with Negribreen (lower NAMM), leave the future state of Ordonnansbreen uncertain as
 519 the NGS surge continues to progress.

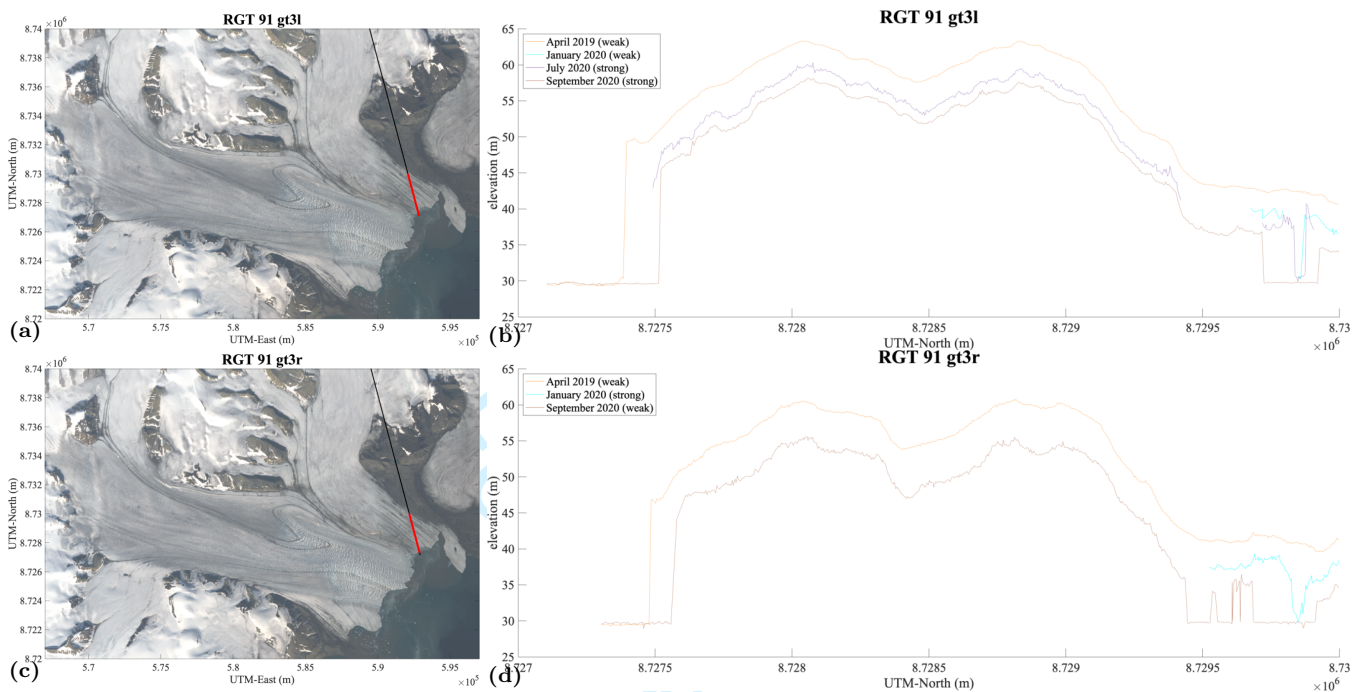

Fig. 15. DDA-ice results over Ordonnansbreen's terminus and the Ordonnansbreen tooth, 2019-2020. (a)-(b) RGT 91 gt3l shows the disintegration of Ordonnansbreen's terminus at its northern edge, i.e., at the tooth, above 8.729e6 UTM-North. (c)-(d) RGT 91 gt3r also displays the signal of a disintegrating northern terminus of Ordonnansbreen. Both time series also show significant surface lowering across the terminus width.

520 4.3.4. Changes in the Ice Falls between the Filchnerfonna and Upper Negribreen

521 The ice falls between Filchnerfonna and upper Negribreen have been areas of pervasive change during the
 522 2019-2020 part of the surge in the NGS, as observed during our 2019 field campaign (Herzfeld and others,
 523 2022). While ice falls are characterized by heavy crevassing due to steep topography, the imprint of the
 524 surge manifests through fresh crevasse openings along with the widening and deepening of existing crevasses.
 525 Figure 16 shows distinct signs of activity in the ice falls, indicative of expansion of the surge-affected area
 526 beyond the NGS. Surge activity is most pronounced in the southern ice falls where increased crevassing
 527 occurs (Figures 16(b),(d)). Increased crevassing is not as prevalent along the inflowing Transparentbreen,
 528 which is less steep than the other inflowing glaciers from Filchnerfonna, however, there is a pronounced
 529 surface lowering across its entire width. The rate of surface-height lowering here is increasing as seen by the
 530 spacing of the later 2020 lines (purple, brown) compared to the earlier 2019 lines (yellow, green), indicating
 531 building surge effects on Transparentbreen.

532 An important observation in the context of expansion of the surge beyond the NGS, our results motivate
 533 the question whether the surge in the NGS may induce a disintegration of the surrounding glacial area,
 534 potentially destabilizing the Filchnerfonna. A less dramatic interpretation is that significant surface lowering
 535 in the NGS leads to draw-down of ice flowing through the ice falls. Either way, the surge in the NGS is
 536 affecting adjacent ice areas at the border of its accumulation zone.

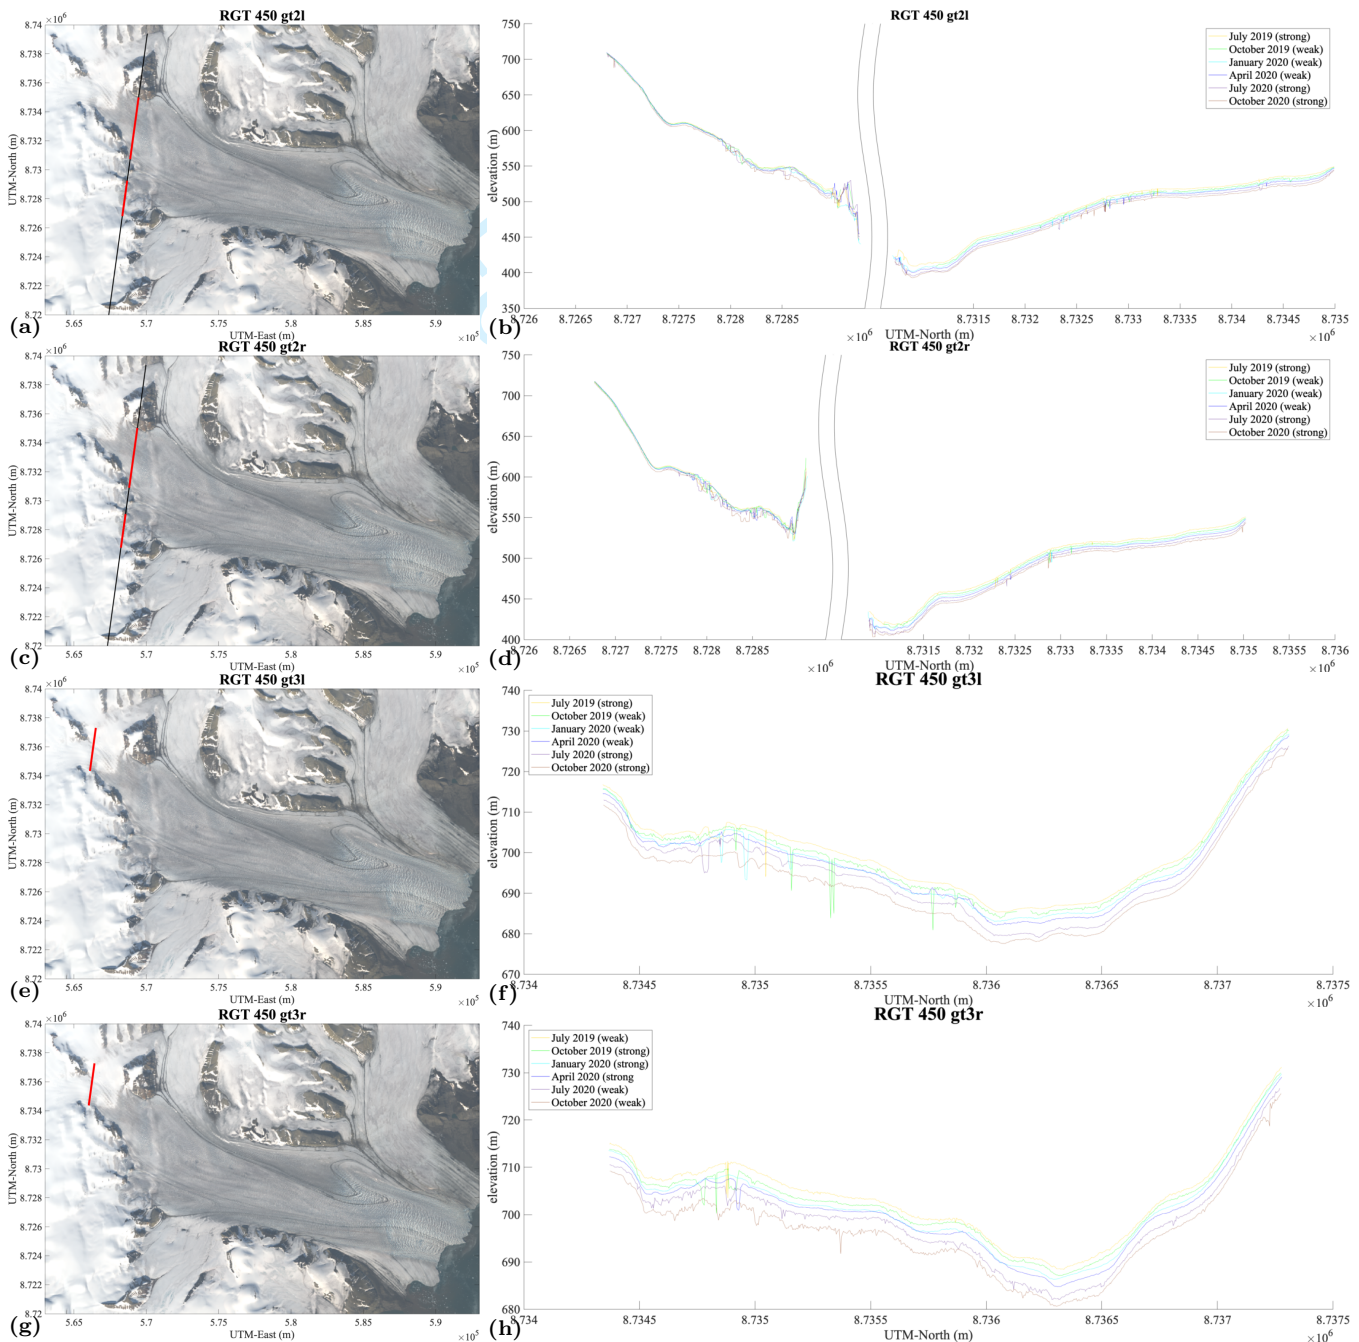

Fig. 16. DDA-ice results near the inflow from Filchnerfonna, 2019-2020. (a)-(b) RGT 450 gt2l surveying both the southern ice falls and Transparentbreen in the north, (c)-(d) RGT 450 gt2r surveying the ice falls and Transparentbreen, (e)-(f) RGT 450 gt3l surveying only Transparentbreen, and (g)-(h) RGT 450 gt3r also surveying only Transparentbreen.

537 4.3.5. General Mass Transfer Observations

538 The surface height changes of 2019-2020 given by Figure 8, reflect significant mass transfer from the
539 reservoir area in upper and mid Negribreen down-glacier to the receiving area in the lower glacier within
540 5 km of the terminus. The ice-mass transferred to the receiving area is eventually transported to the Arctic
541 Ocean via heavy calving during the surge. These mass transfer observations are further detailed in the
542 analysis of surface height time series of the proceeding sections.

543 In total, the ICESat-2 results gives a clear indication that the mass transfer is surge induced rather than
544 climatically induced. As seen most clearly in Figures 12(b) and 13(d), surface height profiles overlies each
545 other at the beginning and end of each track (i.e., on the non-surgingly tributary glaciers on the sides of
546 Negribreen) but significant height change is apparent along the interior of the profile. If surface lowering
547 were climatically caused (mass loss through melting), then similar height changes between 2019 and 2020
548 would be observed across the entire profile.

549 5. CONCLUSIONS

550 In this paper, we have derived information on geophysical processes that occurred during the surge of
551 Negribreen Glacier System based on analysis of 2 years of ICESat-2 ATLAS data from 2019 and 2020,
552 processed with the DDA-ice. ICESat-2 data, analyzed with the DDA-ice, provide a unique and novel
553 capability to obtain geophysical information on high resolution height changes during a glacier surge from
554 spaceborne altimeter observations. The NGS provides an ideal study region as the main acceleration phase
555 of the surge overlaps with the observation phase of the ICESat-2 mission. Negribreen's surge started in 2016,
556 with peak acceleration in 2017, while ICESat-2 launched on 15 September 2018. Here we have analyzed
557 all ICESat-2 data collected between January 2019 and December 2020 over Negribreen to demonstrate our
558 approach. The analysis is supplemented with velocity maps from Sentinel-1 SAR imagery and airborne
559 data from our August 2019 campaign to Negribreen.

560 Geophysical information on the evolution of the surge is derived from the ICESat-2/DDA-ice high
561 resolution data, including: crevassing, height changes, mass transfer toward the terminus and roughness
562 changes indicative of evolving crevasse fields. Height-change rates in 2019-2020 range from -30m/yr in
563 the reservoir areas of upper Negribreen, to +30 m/yr in the receiving area in the lower glacier near the
564 terminus. Roughness change maps indicate an expansion of the surge in upper Negribreen, particularly
565 near the shear margins, while surge activity in the lower glacier lessened from 2019 to 2020.

566 Time series analysis of ICESat-2 profiles, analyzed with the DDA-ice, indicates formation of new crevasse
567 fields and expansion of existing crevasse fields, as the surge progresses and affects larger areas of the NGS.
568 The increased surge activity from 2019 to 2020 in the upper glacier is especially seen on the inflowing
569 glaciers from the Filchnerfonna accumulation zone, and along the Negribreen-Akademikarbreen Medial
570 Moraine, which divides the surging ice of Negribreen and the non-surging ice of the northern tributary
571 glaciers.

572 The fresh surge crevassing along and across the NAMM in the mid and upper glacier in 2019-2020
573 indicates disintegration along the shear margin and reflects a continuation of the deformational process
574 that resulted in a “retreating bay”, an area of open water filled with melange that formed as a result of
575 a strong force gradient along the shear margin between the surging ice of Negribreen and non-surging ice
576 of neighboring Ordonnansbreen, near the terminus in 2017. Occurrence of water in crevasses that reaches
577 almost to the ice surface height was observed near the upper NAMM in August 2019, just before the new
578 crevasses were formed. Furthermore, our analysis of surge progression in 2019-2020 provided detailed height
579 information on the separation process of a segment of lower Ordonnansbreen (“Ordonnansbreen tooth”)
580 from the main glacier along a rift that had formed during the surge.

581 Large-scale mass transfer, extensive roughness changes, and the striking disintegration along the NAMM,
582 and of Ordonnansbreen’s tooth and the lower glacier as a whole, clearly illustrate the rapid surface change
583 and mass loss a glacier can experience during a surge. These results demonstrate the novel capability
584 of ICESat-2, analyzed with the DDA-ice, to provide high-resolution height data uniquely capable of
585 documenting these complex surge processes from space.

586 DATA AVAILABILITY

587 (1) ICESat-2 data products, e.g. ATL03, are freely available through NASA at <https://earthdata.nasa.gov/>
588 (release 4 used in this paper) and is provided by the National Snow and Ice Data Center (NSIDC).
589 (2) Data collected as part of the Negribreen Airborne Geophysical Campaigns, collected by the authors
590 and their extended team, are available through the NSF Arctic Data Center and can be accessed
591 at <https://arcticdata.io/data/10.18739/A2QF8JK7T> (Herzfeld and Trantow, 2021). (3) Sentinel-1 SAR
592 data are freely available through the the European Space Agency’s Copernicus Open Access Hub
593 (<https://scihub.copernicus.eu/>). (4) Landsat-8 data are freely available through the U.S. Geological Survey,
594 e.g., through the USGS Global Visualization Viewer (GloVis), (<https://glovis.usgs.gov/>).

595 ACKNOWLEDGEMENTS

596 Thanks are due to our pilot and technician, Harald Sandal and Gustav Svanstrom, Airlift, Norway, of the
597 2019 Negribreen campaign, to Matt Lawson, Geomathematics Group, University of Colorado Boulder,
598 for help with data collection in 2019, to Jack Kohler, Geir Ove Aspnes, Jørn Dybdahl, Norwegian
599 Polar Institute, to Chris Borstad, University Center in Svalbard (UNIS), now University of Montana, to
600 Thomas Nylen and UNAVCO Boulder for GPS support, to Inger Jennings (SIOS) and Kristin Woxholth,
601 Longyearbyen, for help with logistical support, to the ICESat-2 Project, especially Thomas Neumann,
602 Kaitlin Harbeck, David Hancock and Anthony Martino for collaboration and support regarding ICESat-
603 2, to Huilin Han and Rachel Middleton, Geomathematics Group, University of Colorado Boulder, for
604 derivation of some of the velocity maps from Sentinel-1 SAR data and to the European Space Agency for
605 providing the SNAP tool for velocity-map calculation.

606 Research and data collection were supported by the U.S. National Aeronautics and Space Administration
607 (NASA) Earth Sciences Division under awards 80NSSC20K0975, 80NSSC18K1439 and NNX17AG75G and
608 by the U.S. National Science Foundation (NSF) under awards OPP-1745705 and OPP-1942356 (Office of
609 Polar Programs) and OAC-1835256 (Office of Advanced Cyberinfrastructure); Principal Investigator for
610 all awards is Ute Herzfeld. The helicopter was provided by the Norwegian Polar Institute and operated
611 by Airlift. Collection of airborne data was conducted with permission of the National Security Authority
612 of Norway, the Civil Aviation Authority of Norway and the Governor of Svalbard, registered as Research
613 in Svalbard Project RIS-10827 "NEGRIBREEN SURGE". The data collection was also partly supported
614 through a 2018 Access Pilot Project (2017_0010) of the Svalbard Integrated Observing System (SIOS). All
615 this support is gratefully acknowledged.

616 SUPPLEMENTAL MATERIAL

617 The supplementary material for this article can be found at [link TBD]. There are two documents provided:

- 618 1. negri_data_2019_2020.xlsx: A CSV file providing information on the ATL03 granule, acquisition date
619 and run names for each DDA-ice run (one for each beam per pass from 2019-2020). This file contains
620 the information in Table 2 as well.
- 621 2. negri.change.suppl.pdf: A figure file containing a full collection of enlarged ICESat-2 time series plots
622 for all beams and RGTs.

Supplementary Material for Manuscript titled “Progression of the surge in the Negribreen Glacier System from two years of ICESat-2 Measurements”

Thomas Trantow ^{1,*}, Ute C. Herzfeld ¹

¹ Department of Electrical, Energy and Computer Engineering, University of Colorado,
Boulder, Colorado, USA

The supplementary material in this document provides a complete collection of the ICESat-2/DDA-ice time series for each RGT and beam listed in Table 2 of the paper. Time series plots already present in the paper, along with those absent from the main manuscript, are enlarged in here for visibility. In addition, Figure 2 of the main manuscript is given below (Figure 1) for a visual reference for location of the ICESat-2 RGT beams over the Negribreen Glacier System.

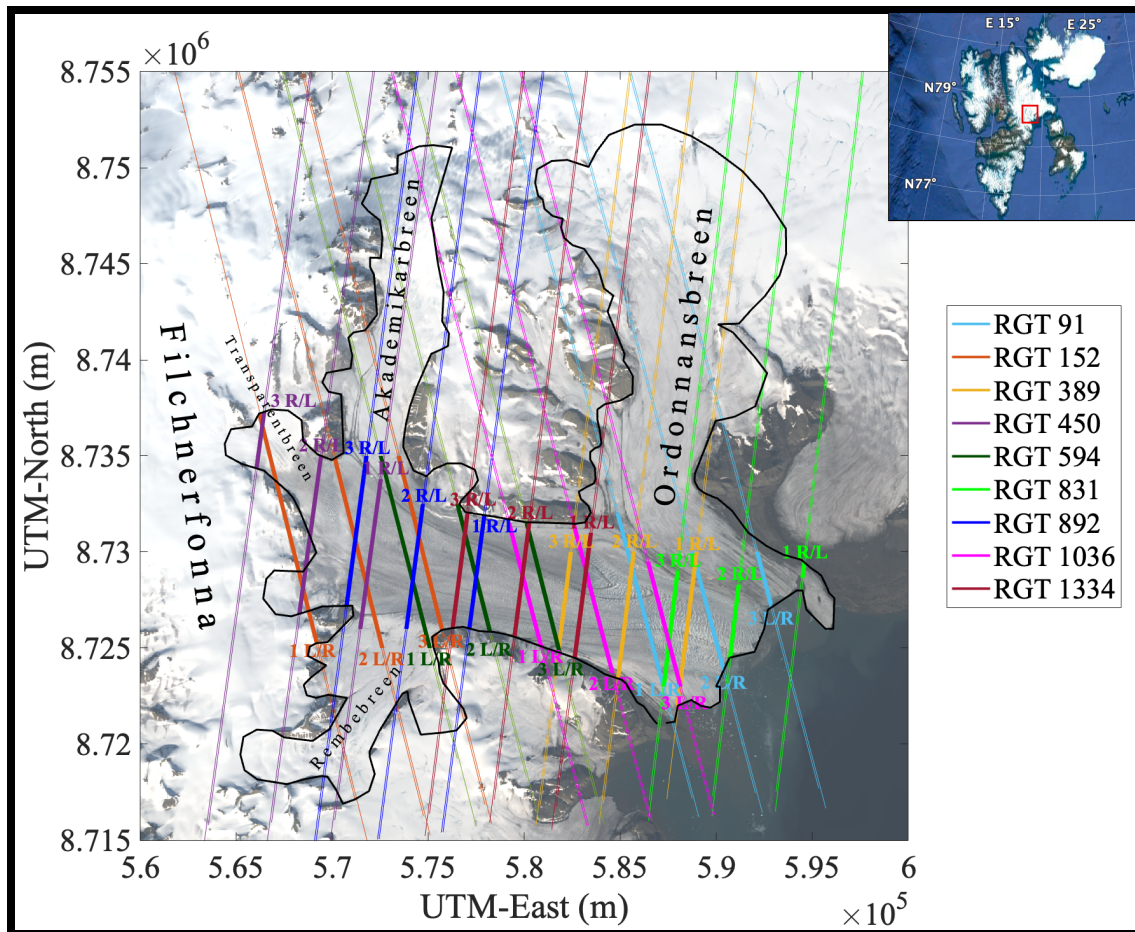

Figure 1: ICESat-2 survey lines over the Negribreen Glacier System. NGS location in the Svalbard archipelago indicated by a red box in the upper right inset. The survey lines for each of ICESat-2's three beam-pairs are color coded by their Reference Ground Track (RGT) while the NGS borders are given by the black line. The thick lines correspond to the part of the track that is analyzed in this paper which is mostly equivalent to the boundaries of Negribreen Glacier Proper. Left/Right (L/R) beam-pairs are separated by ~ 90 m on-ice which is within line thickness over Negribreen proper in this figure. Background image from Landsat-8 acquired 2019-08-05.

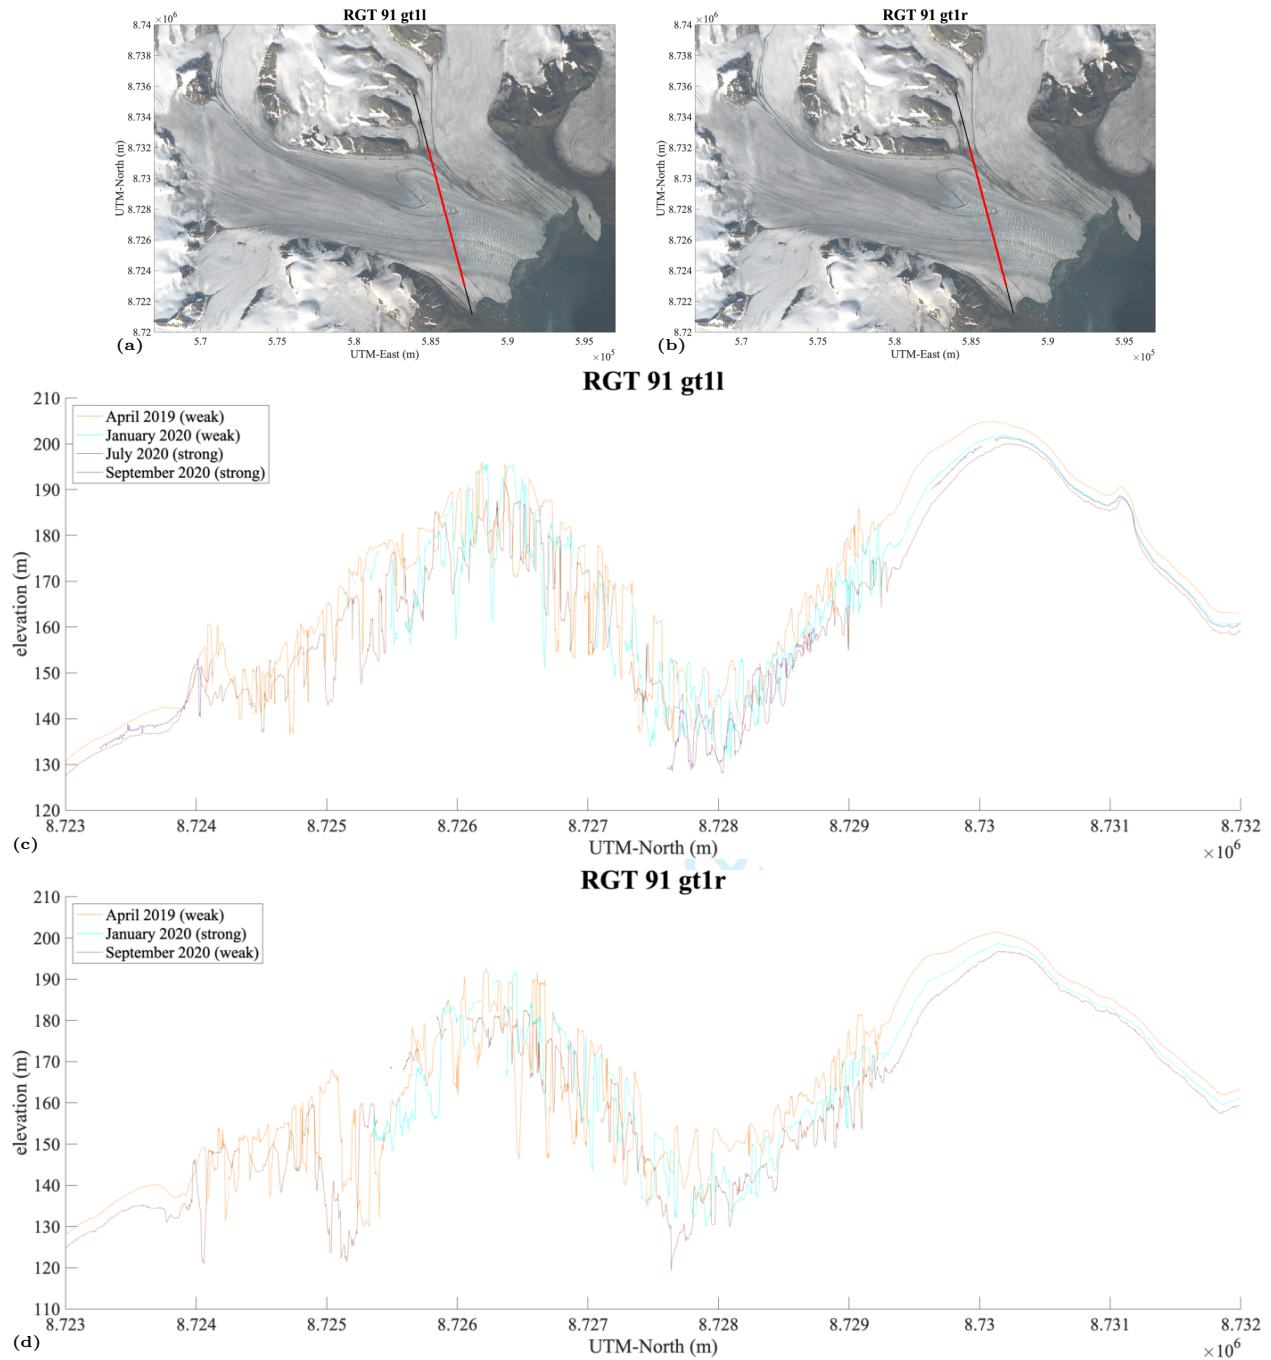

Figure 2: ICESat-2/DDA-ice surface height time series for RGT 91 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 91 gt1l segment over Negribreen, (b) Location of RGT 91 gt1r segment over Negribreen, (c) surface height time series of RGT 91 gt1l, and (d) surface height time series of RGT 91 gt1r.

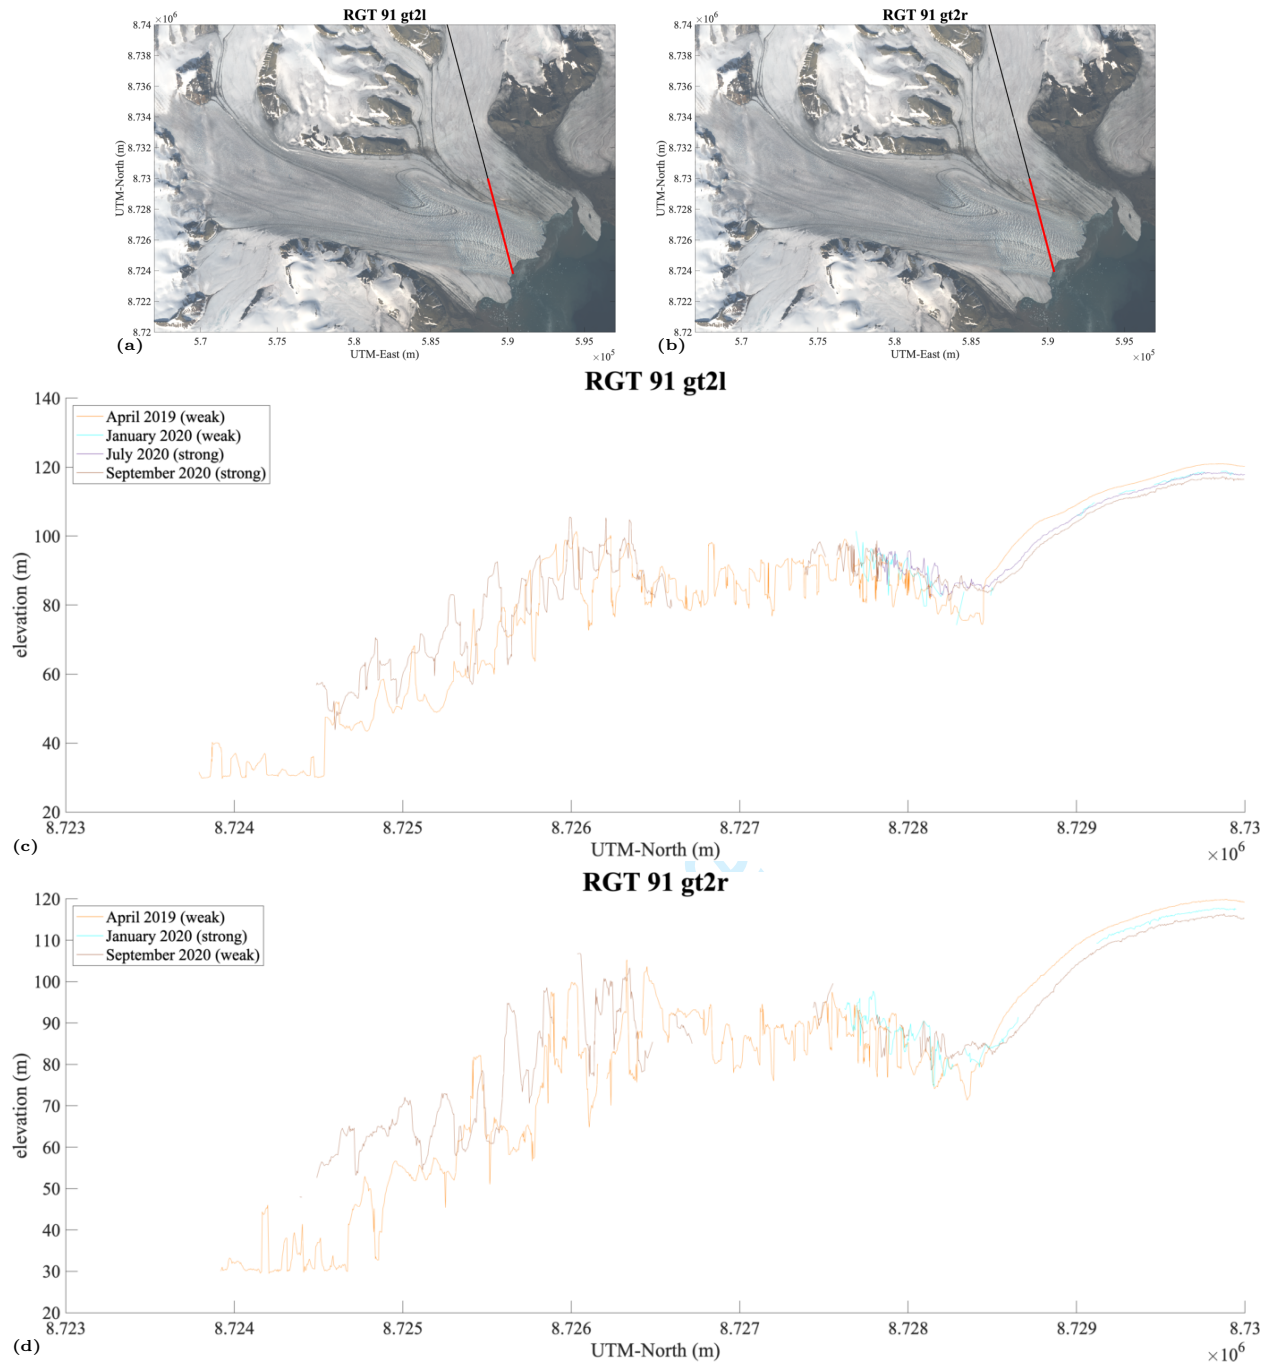

Figure 3: ICESat-2/DDA-ice surface height time series for RGT 91 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 91 gt2l segment over Negribreen, (b) Location of RGT 91 gt2r segment over Negribreen, (c) surface height time series of RGT 91 gt2l, and (d) surface height time series of RGT 91 gt2r.

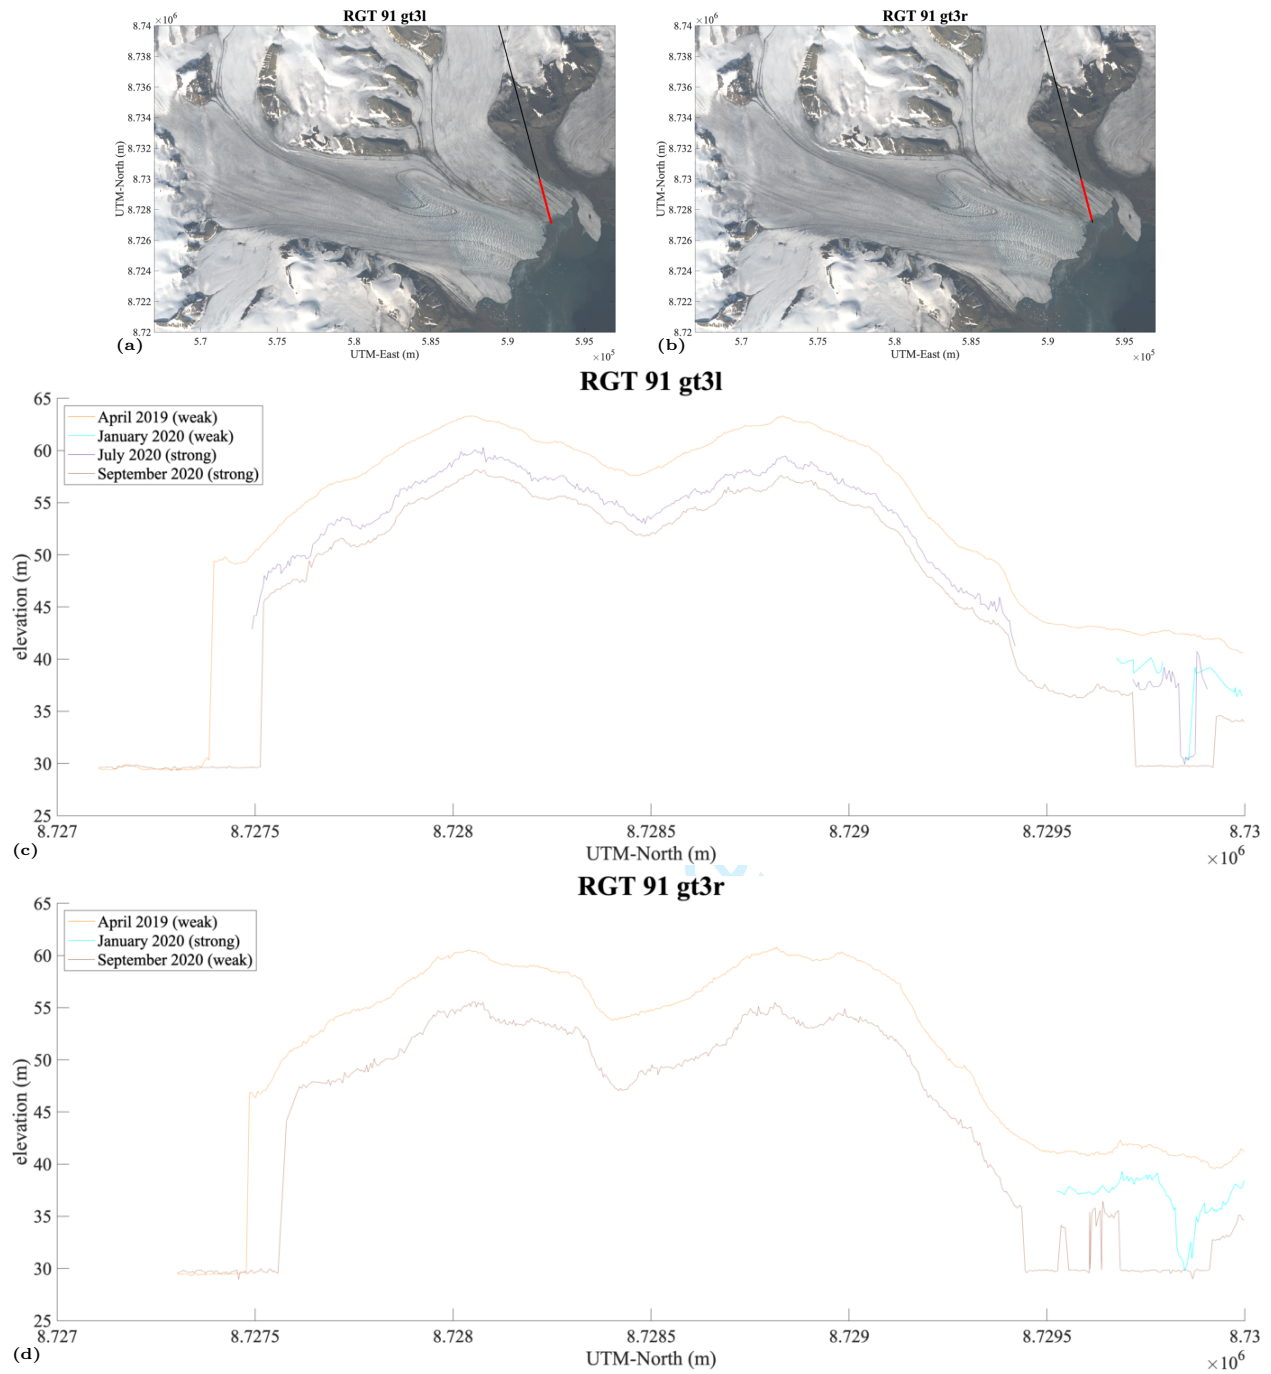

Figure 4: ICESat-2/DDA-ice surface height time series for RGT 91 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 91 gt3l segment over Negribreen, (b) Location of RGT 91 gt3r segment over Negribreen, (c) surface height time series of RGT 91 gt3l, and (d) surface height time series of RGT 91 gt3r.

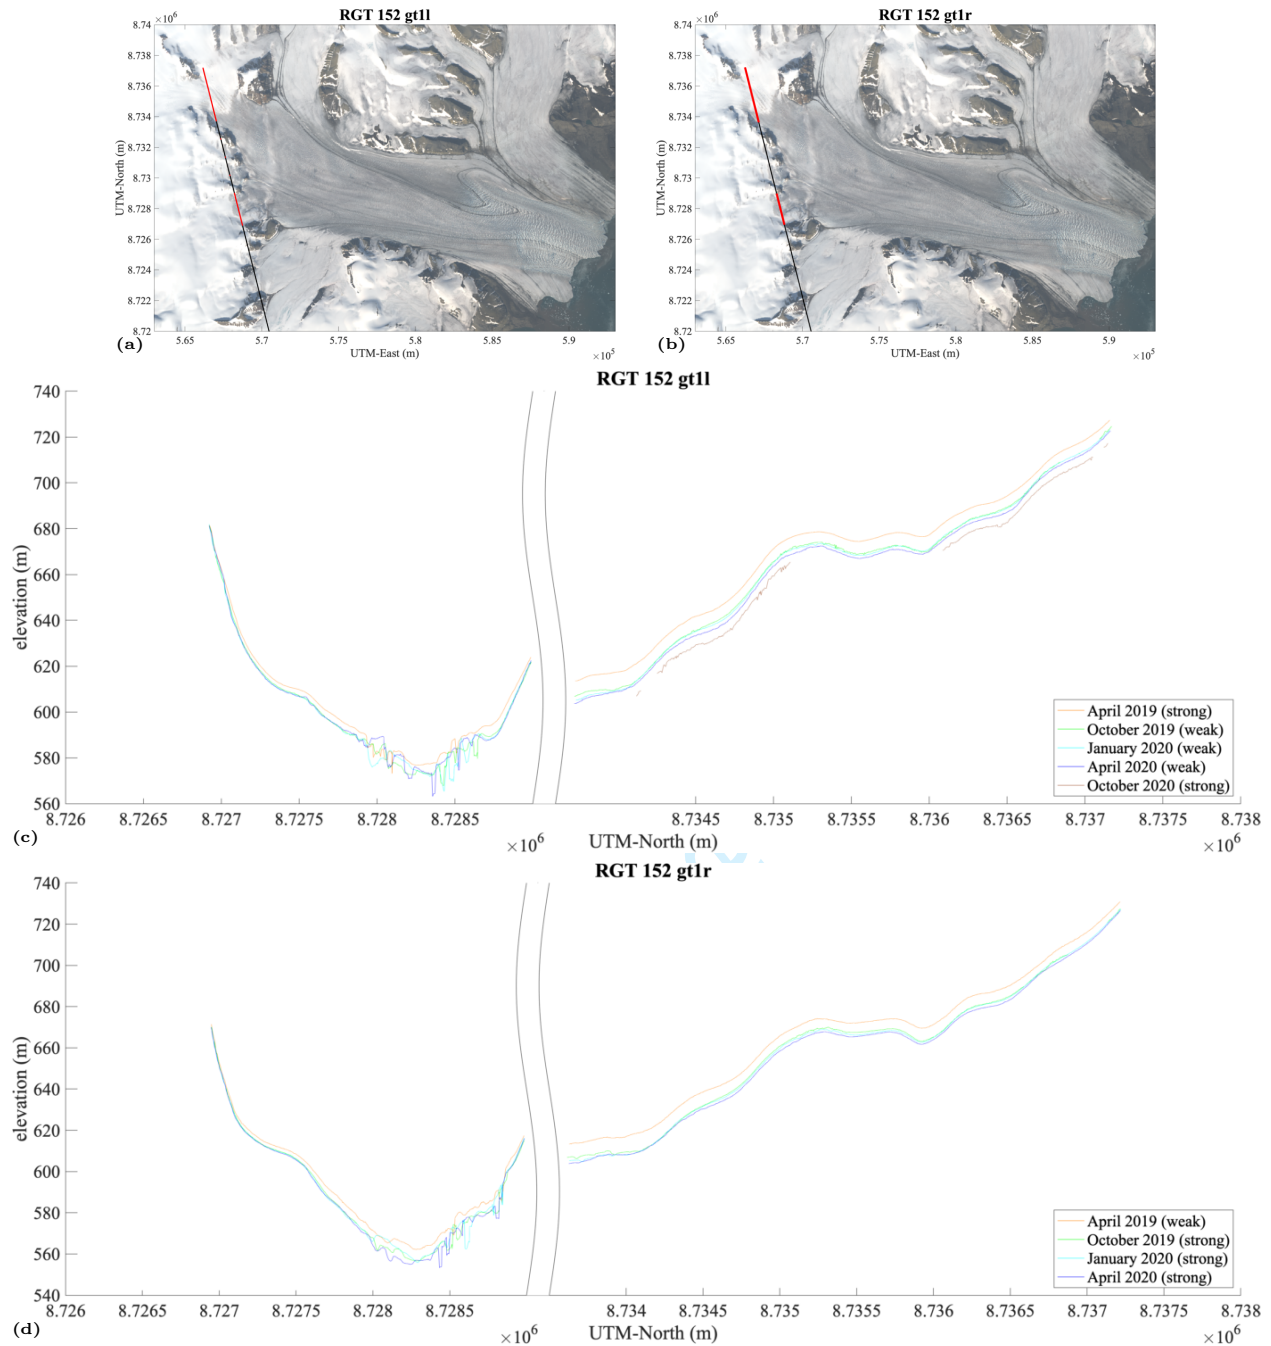

Figure 5: ICESat-2/DDA-ice surface height time series for RGT 152 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 152 gt1l segment over Negribreen, (b) Location of RGT 152 gt1r segment over Negribreen, (c) surface height time series of RGT 152 gt1l, and (d) surface height time series of RGT 152 gt1r.

Figure 6: ICESat-2/DDA-ice surface height time series for RGT 152 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 152 gt1l segment over Negribreen, (b) Location of RGT 152 gt1r segment over Negribreen, (c) surface height time series of RGT 152 gt1l, and (d) surface height time series of RGT 152 gt2r.

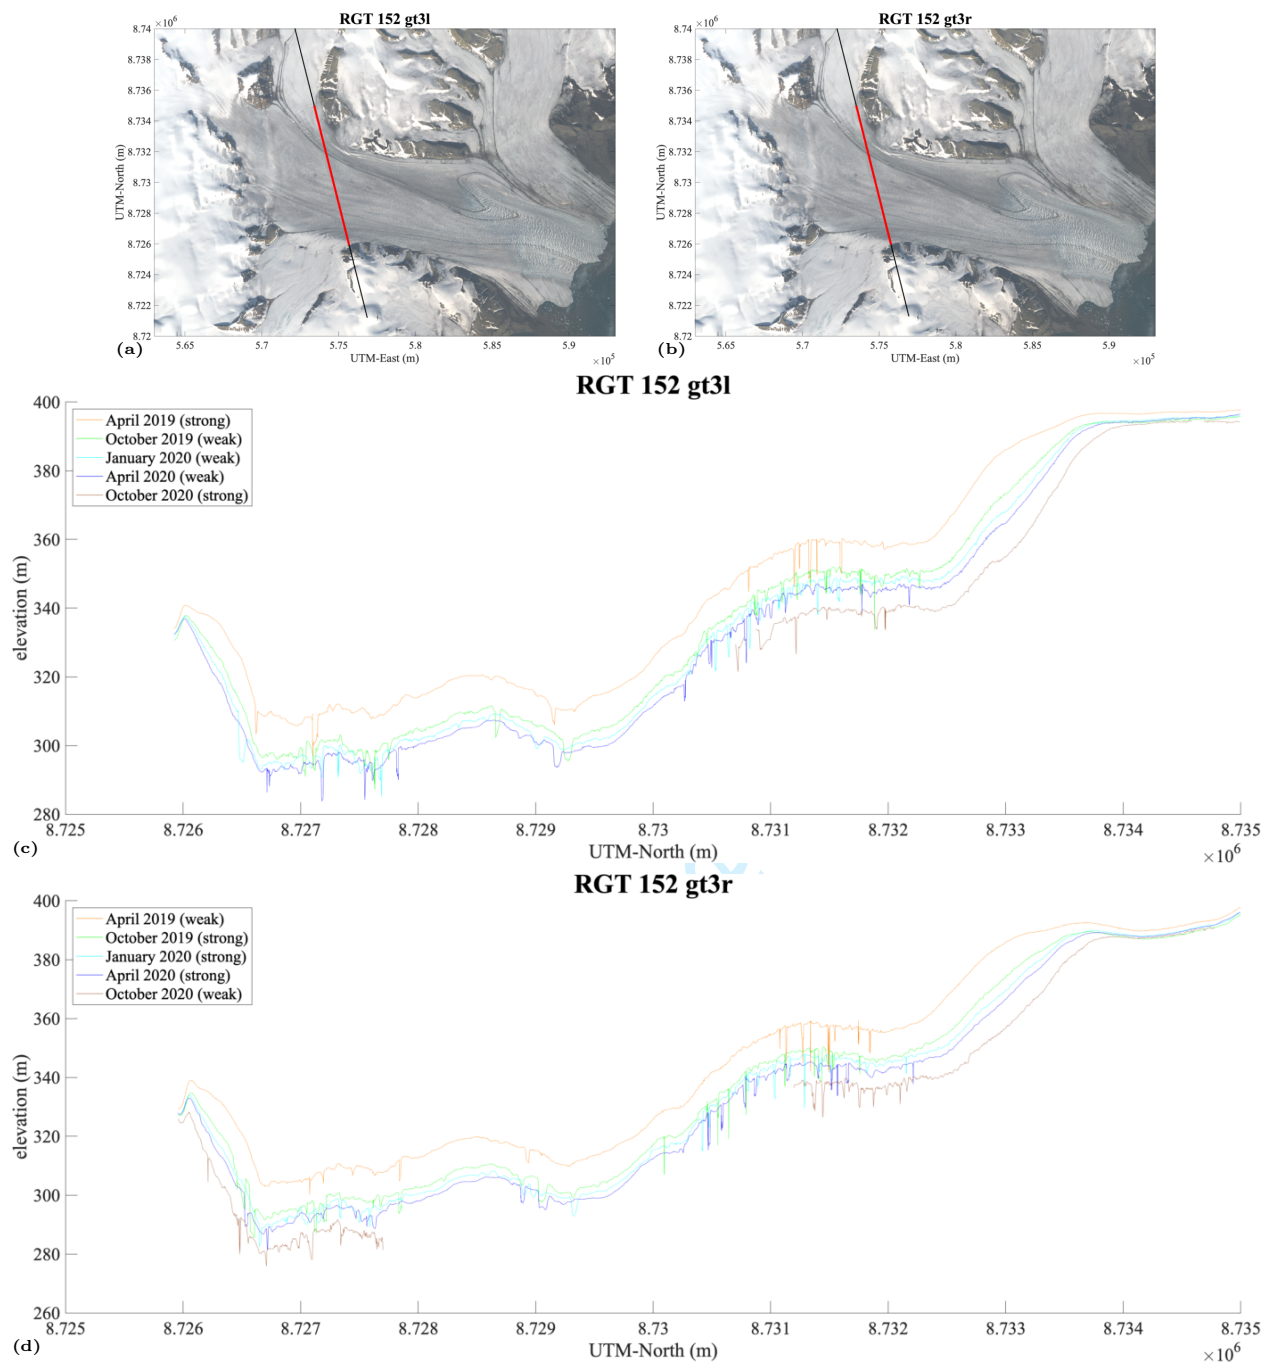

Figure 7: ICESat-2/DDA-ice surface height time series for RGT 152 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 152 gt3l segment over Negribreen, (b) Location of RGT 152 gt3r segment over Negribreen, (c) surface height time series of RGT 152 gt3l, and (d) surface height time series of RGT 152 gt3r.

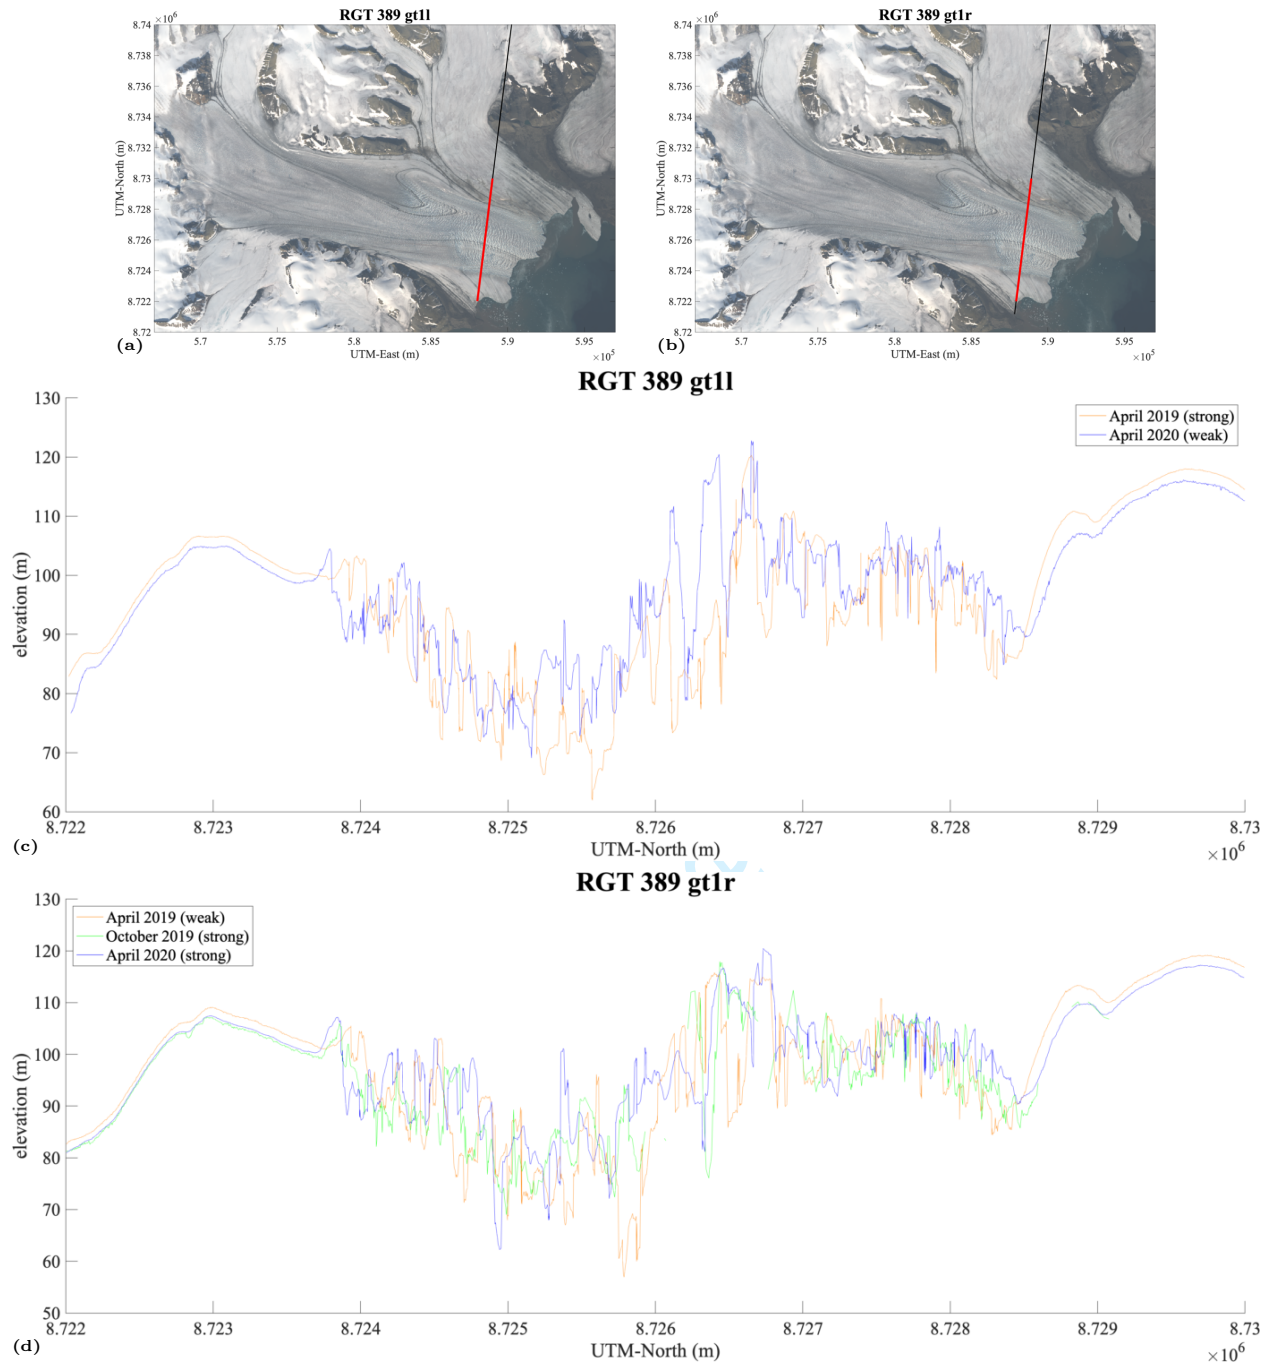

Figure 8: ICESat-2/DDA-ice surface height time series for RGT 389 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 389 gt1l segment over Negribreen, (b) Location of RGT 389 gt1r segment over Negribreen, (c) surface height time series of RGT 389 gt1l, and (d) surface height time series of RGT 389 gt1r.

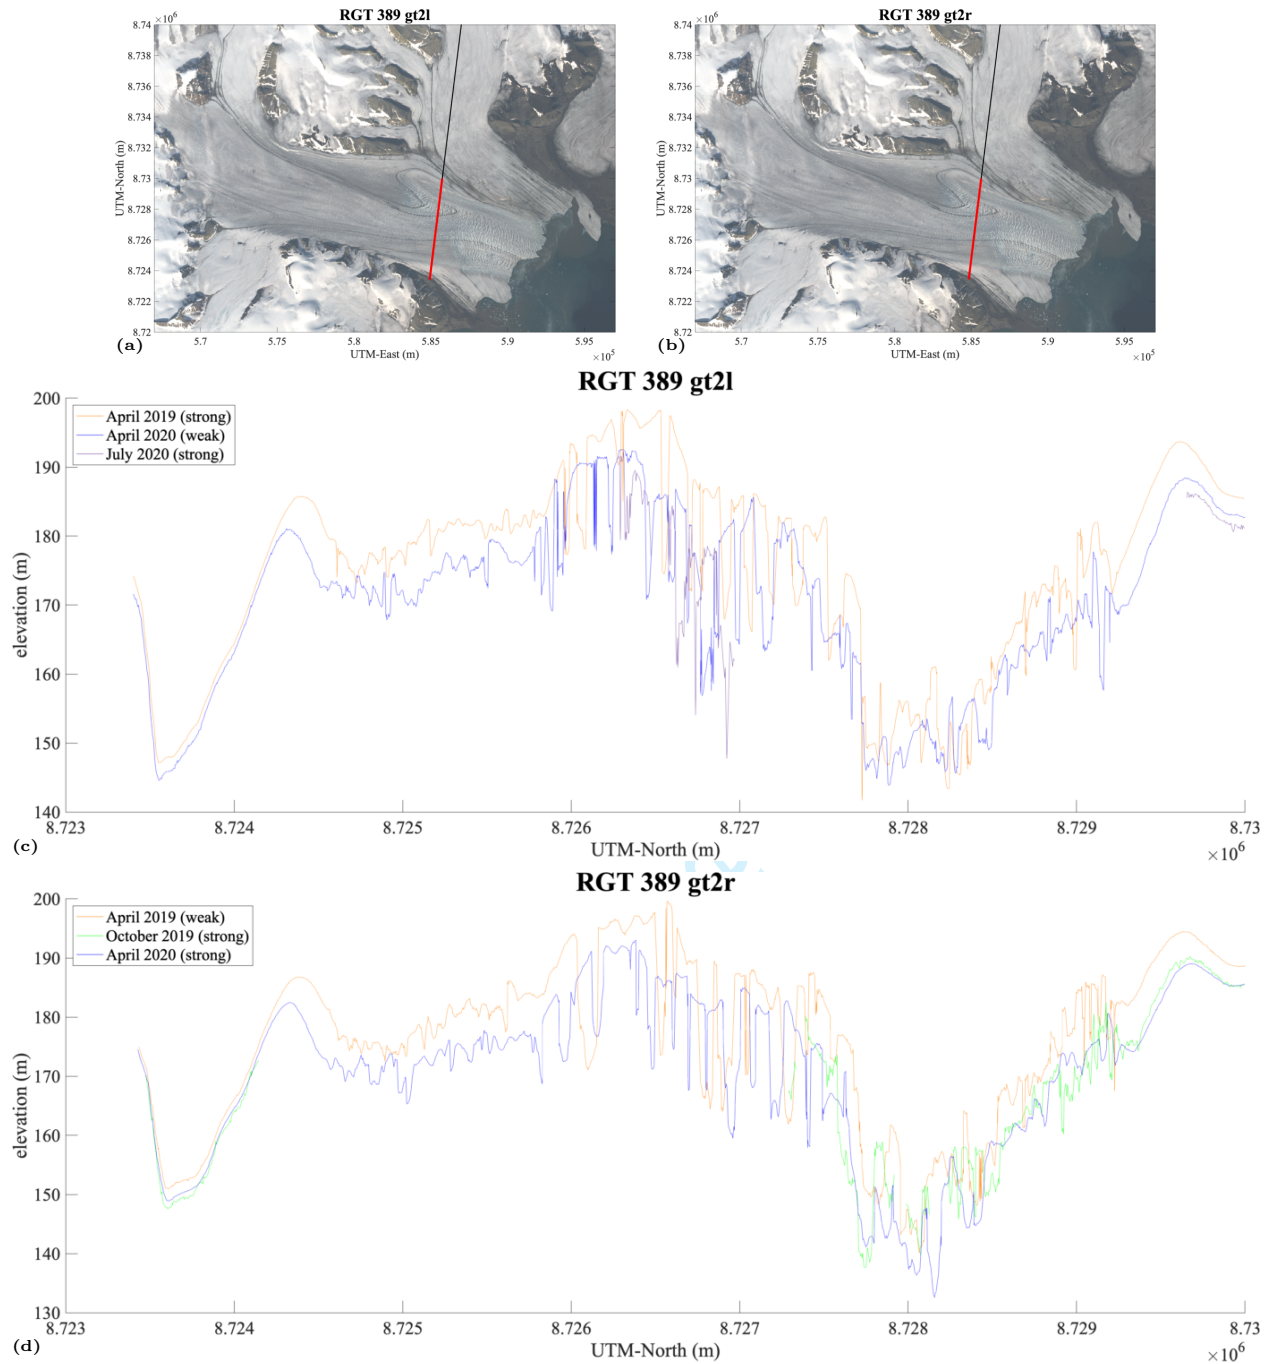

Figure 9: ICESat-2/DDA-ice surface height time series for RGT 389 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 389 gt2l segment over Negribreen, (b) Location of RGT 389 gt2r segment over Negribreen, (c) surface height time series of RGT 389 gt2l, and (d) surface height time series of RGT 389 gt2r.

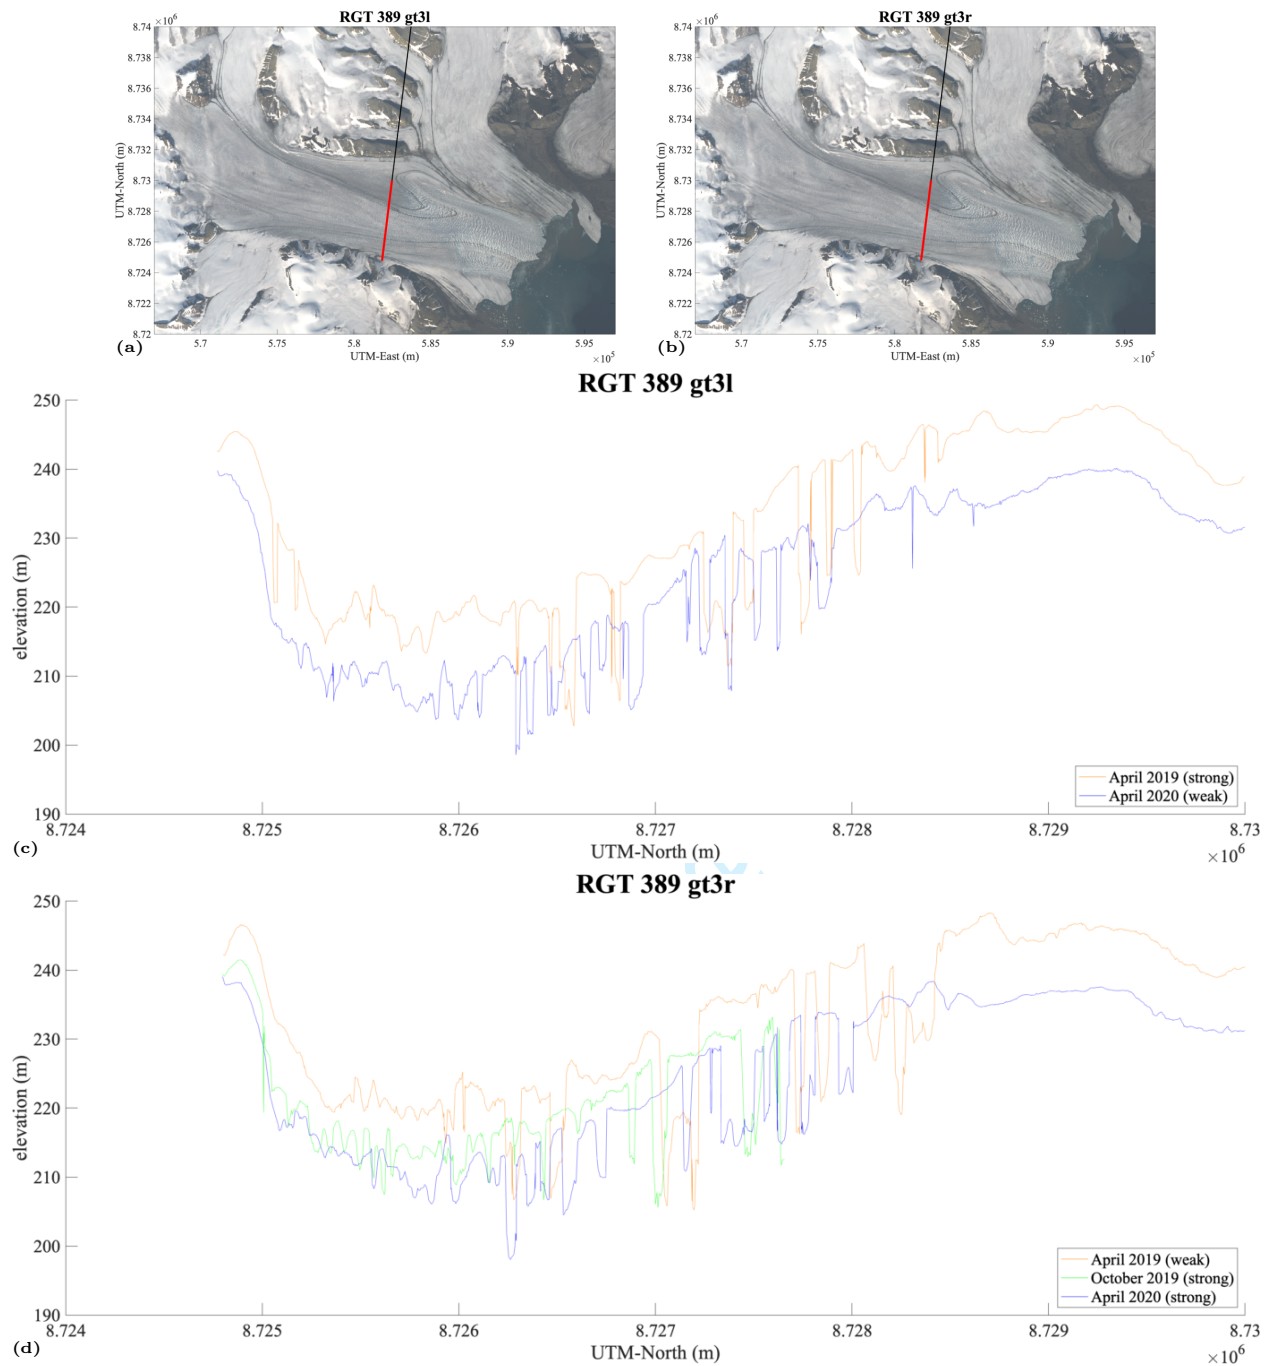

Figure 10: ICESat-2/DDA-ice surface height time series for RGT 389 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 389 gt3l segment over Negribreen, (b) Location of RGT 389 gt3r segment over Negribreen, (c) surface height time series of RGT 389 gt3l, and (d) surface height time series of RGT 389 gt3r.

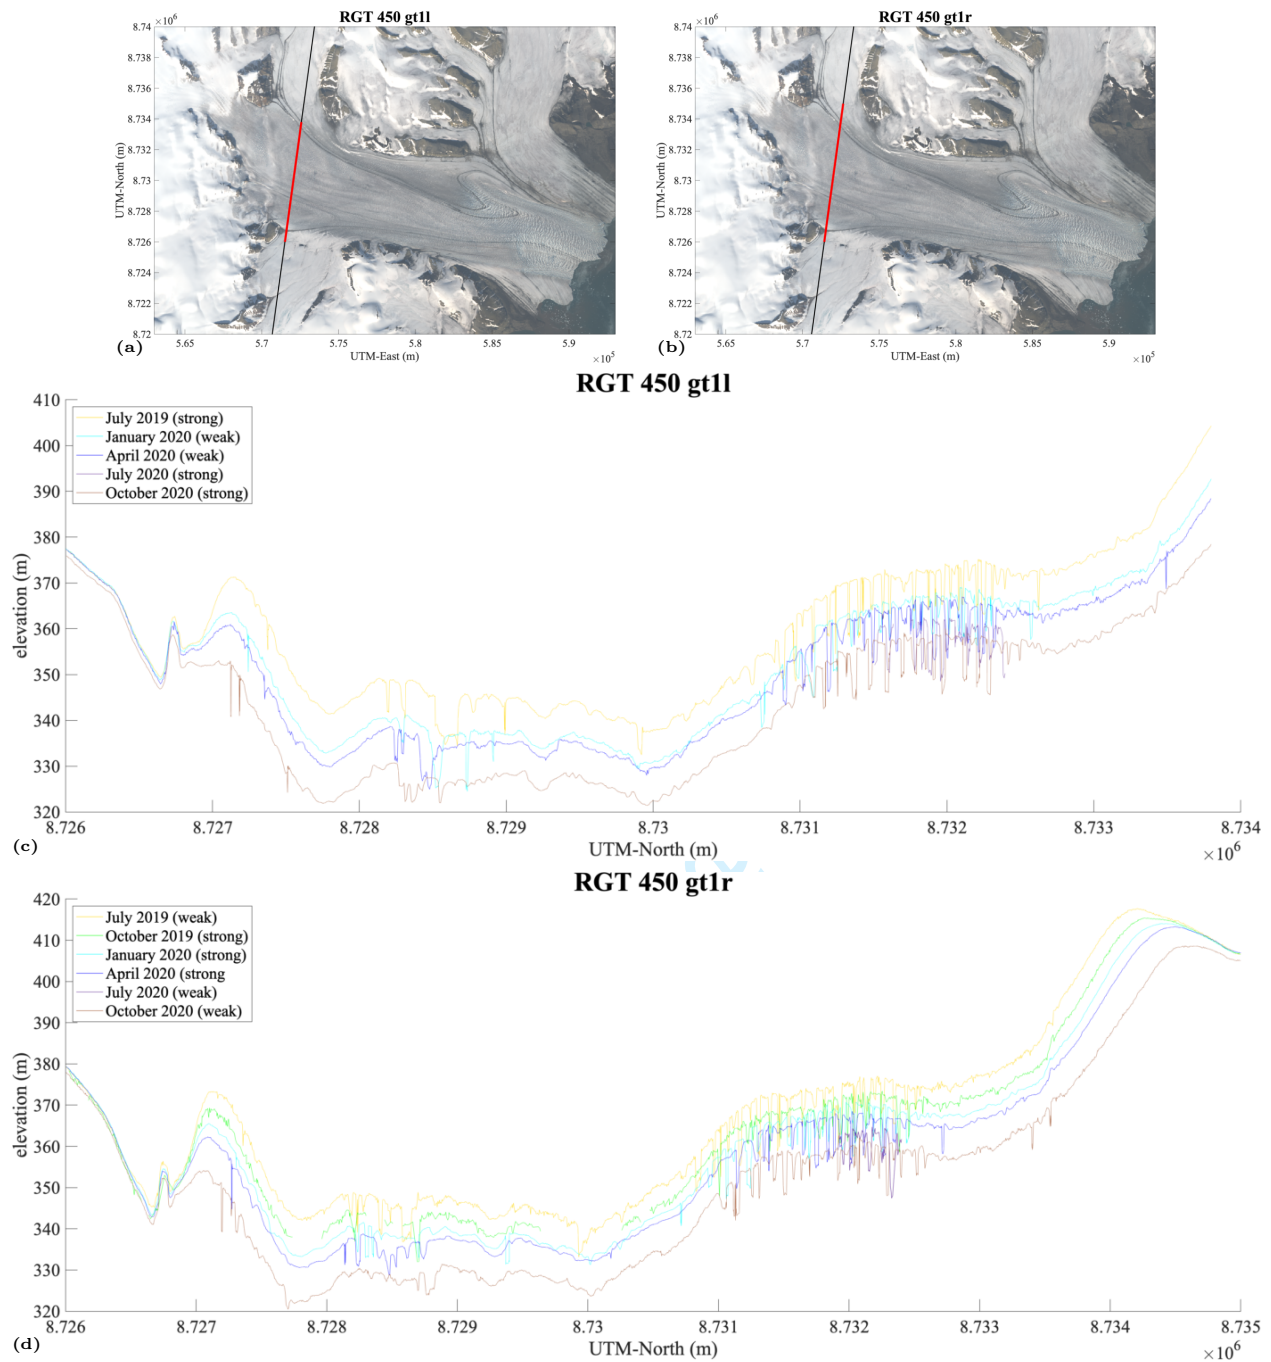

Figure 11: ICESat-2/DDA-ice surface height time series for RGT 450 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 450 gt1l segment over Negribreen, (b) Location of RGT 450 gt1r segment over Negribreen, (c) surface height time series of RGT 450 gt1l, and (d) surface height time series of RGT 450 gt1r.

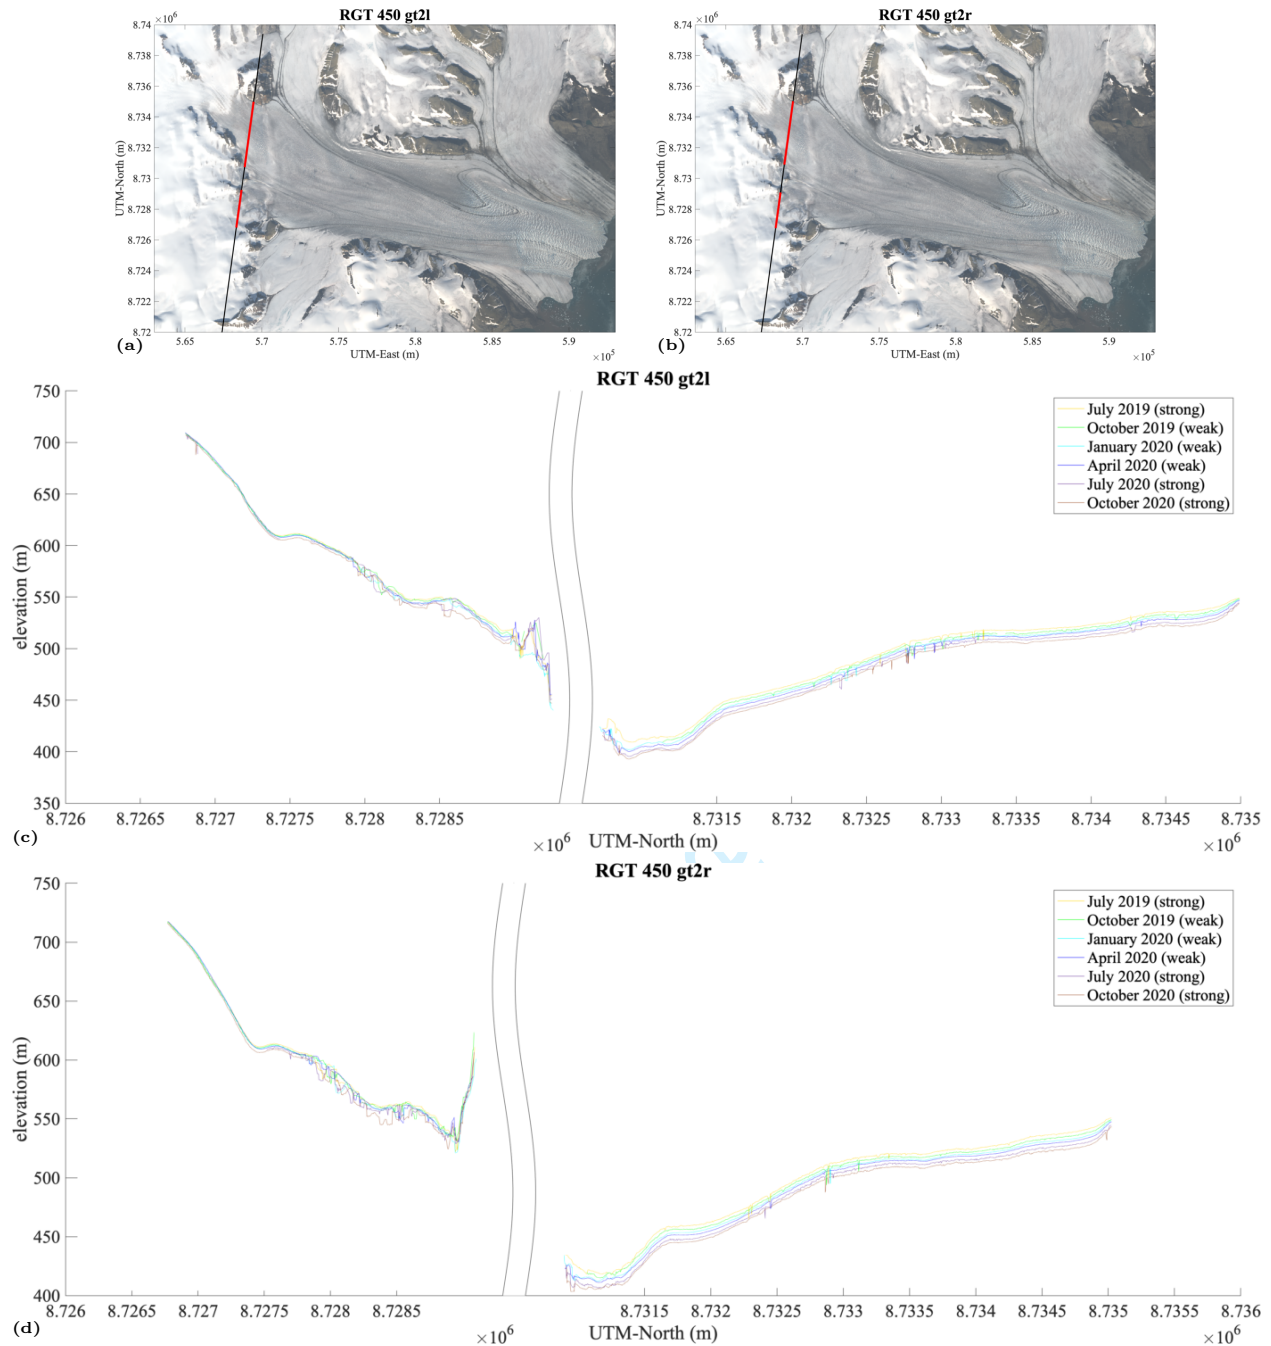

Figure 12: ICESat-2/DDA-ice surface height time series for RGT 450 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 450 gt2l segment over Negribreen, (b) Location of RGT 450 gt2r segment over Negribreen, (c) surface height time series of RGT 450 gt2l, and (d) surface height time series of RGT 450 gt2r.

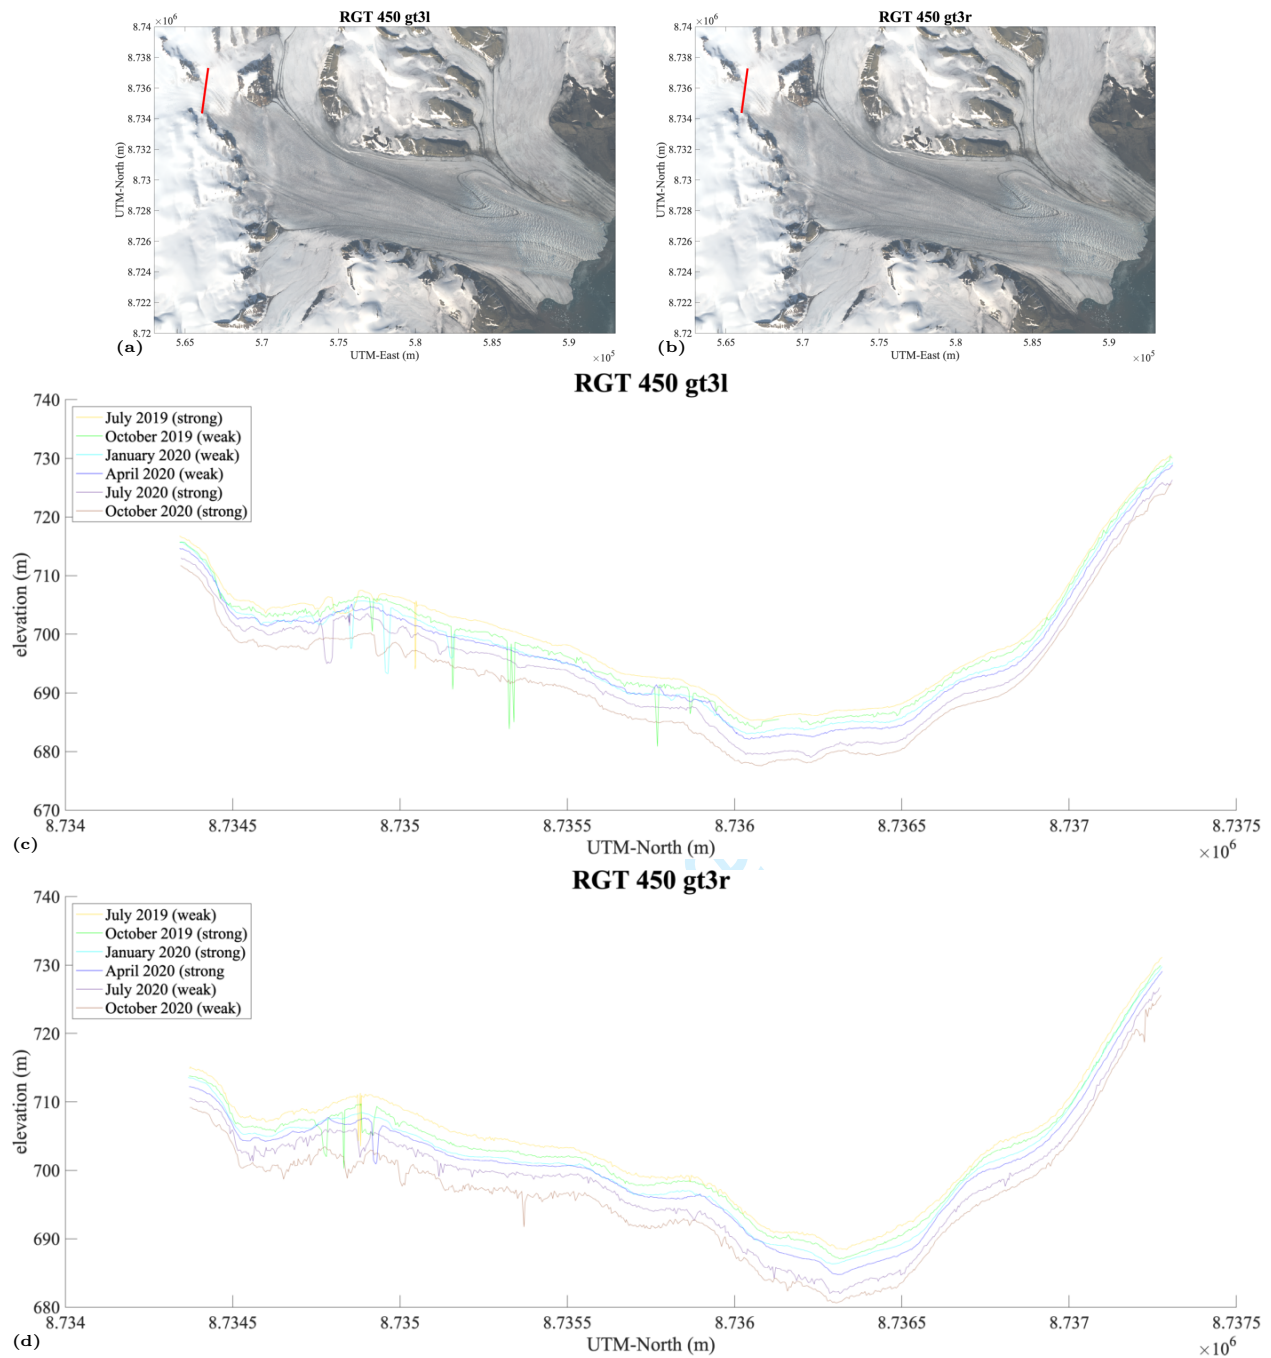

Figure 13: ICESat-2/DDA-ice surface height time series for RGT 450 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 450 gt3l segment over Negribreen, (b) Location of RGT 450 gt3r segment over Negribreen, (c) surface height time series of RGT 450 gt3l, and (d) surface height time series of RGT 450 gt3r.

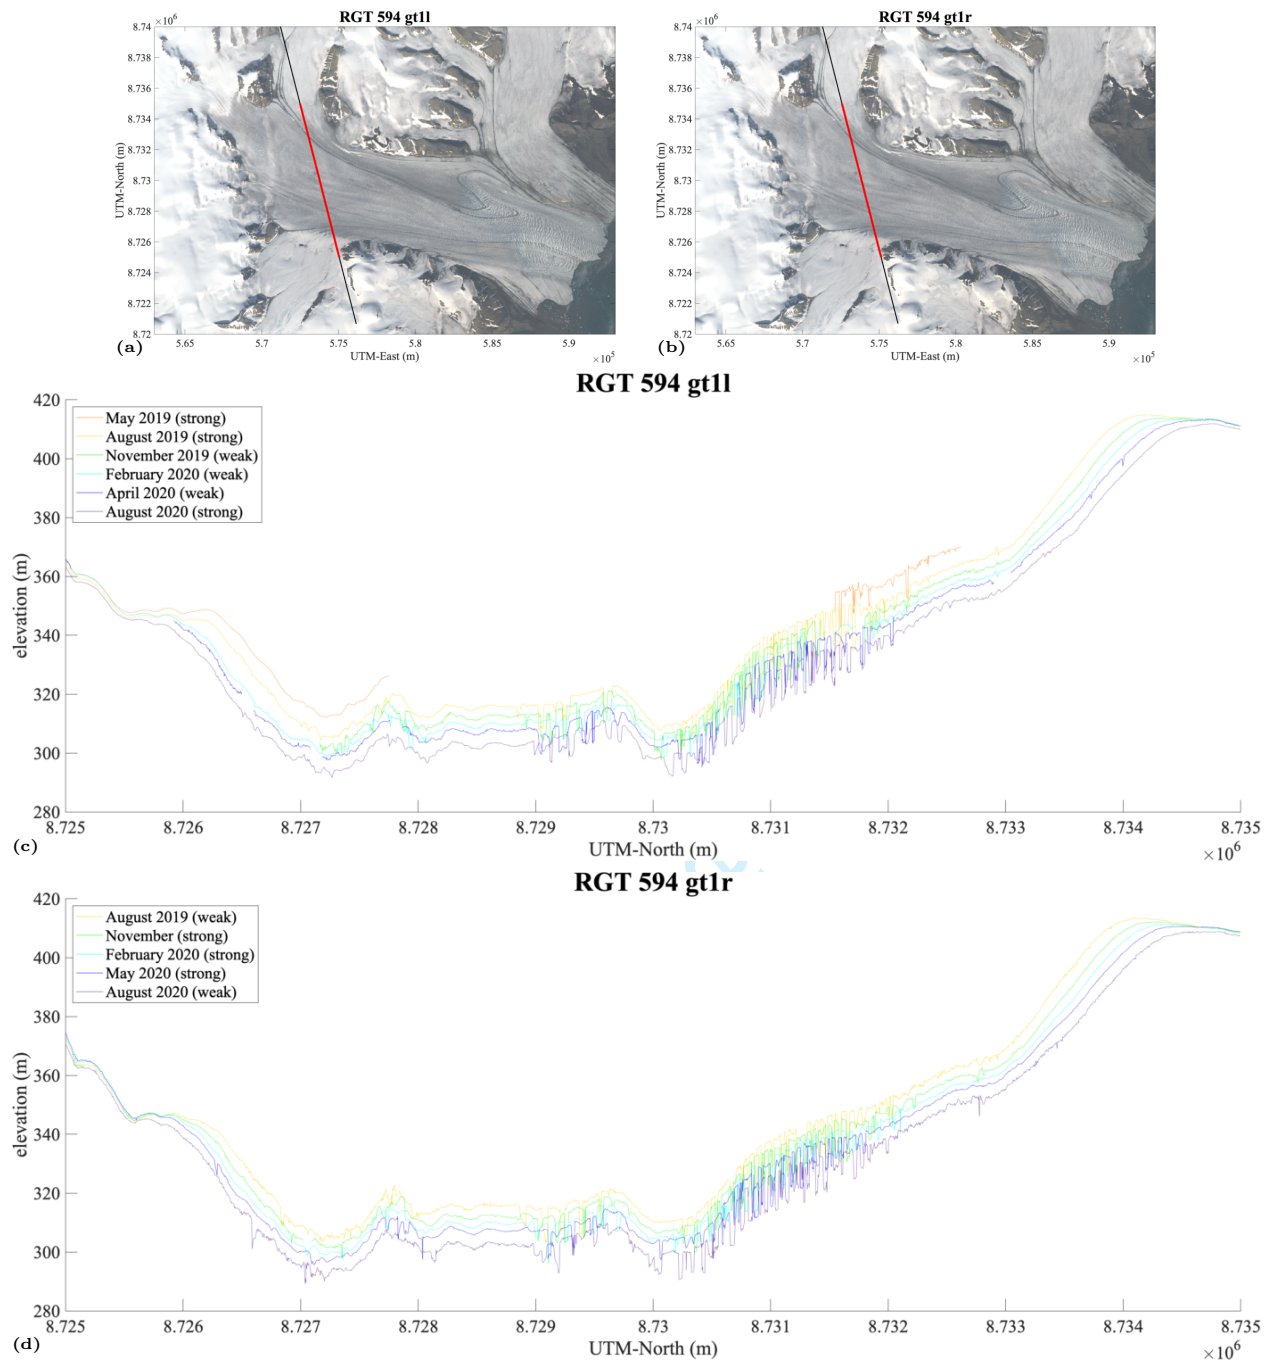

Figure 14: ICESat-2/DDA-ice surface height time series for RGT 594 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 594 gt1l segment over Negribreen, (b) Location of RGT 594 gt1r segment over Negribreen, (c) surface height time series of RGT 594 gt1l, and (d) surface height time series of RGT 594 gt1r.

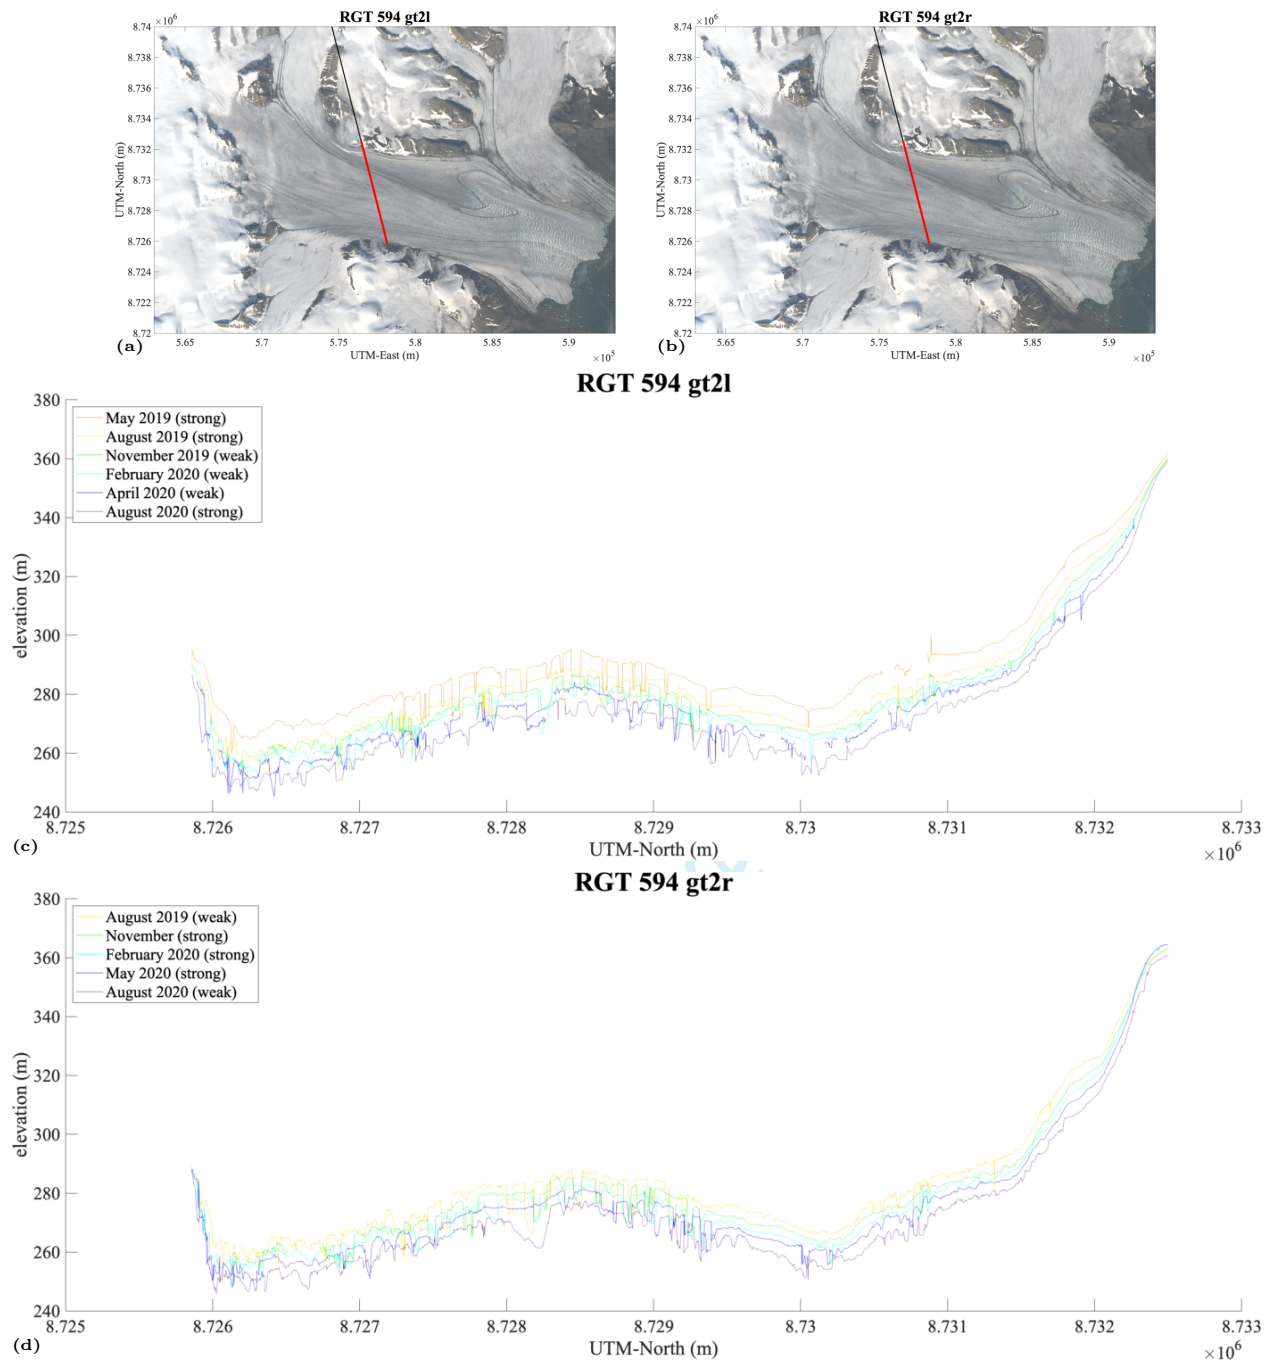

Figure 15: ICESat-2/DDA-ice surface height time series for RGT 594 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 594 gt2l segment over Negribreen, (b) Location of RGT 594 gt2r segment over Negribreen, (c) surface height time series of RGT 594 gt2l, and (d) surface height time series of RGT 594 gt2r.

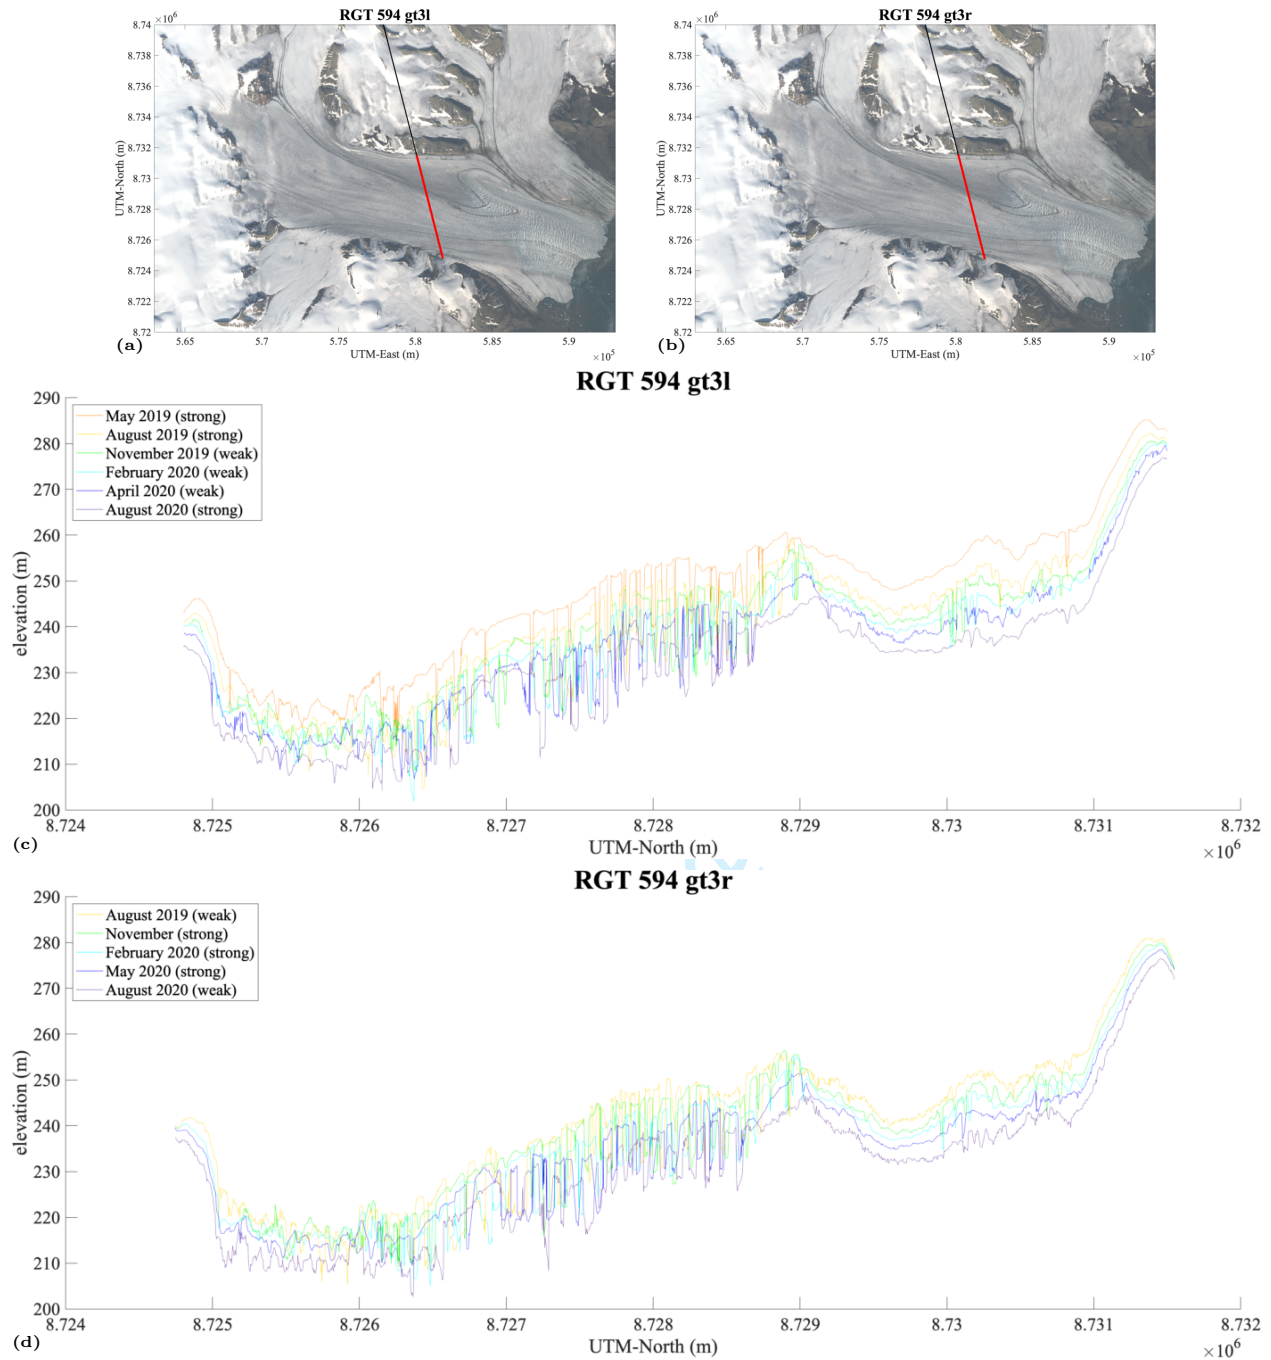

Figure 16: ICESat-2/DDA-ice surface height time series for RGT 594 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 594 gt3l segment over Negribreen, (b) Location of RGT 594 gt3r segment over Negribreen, (c) surface height time series of RGT 594 gt3l, and (d) surface height time series of RGT 594 gt3r.

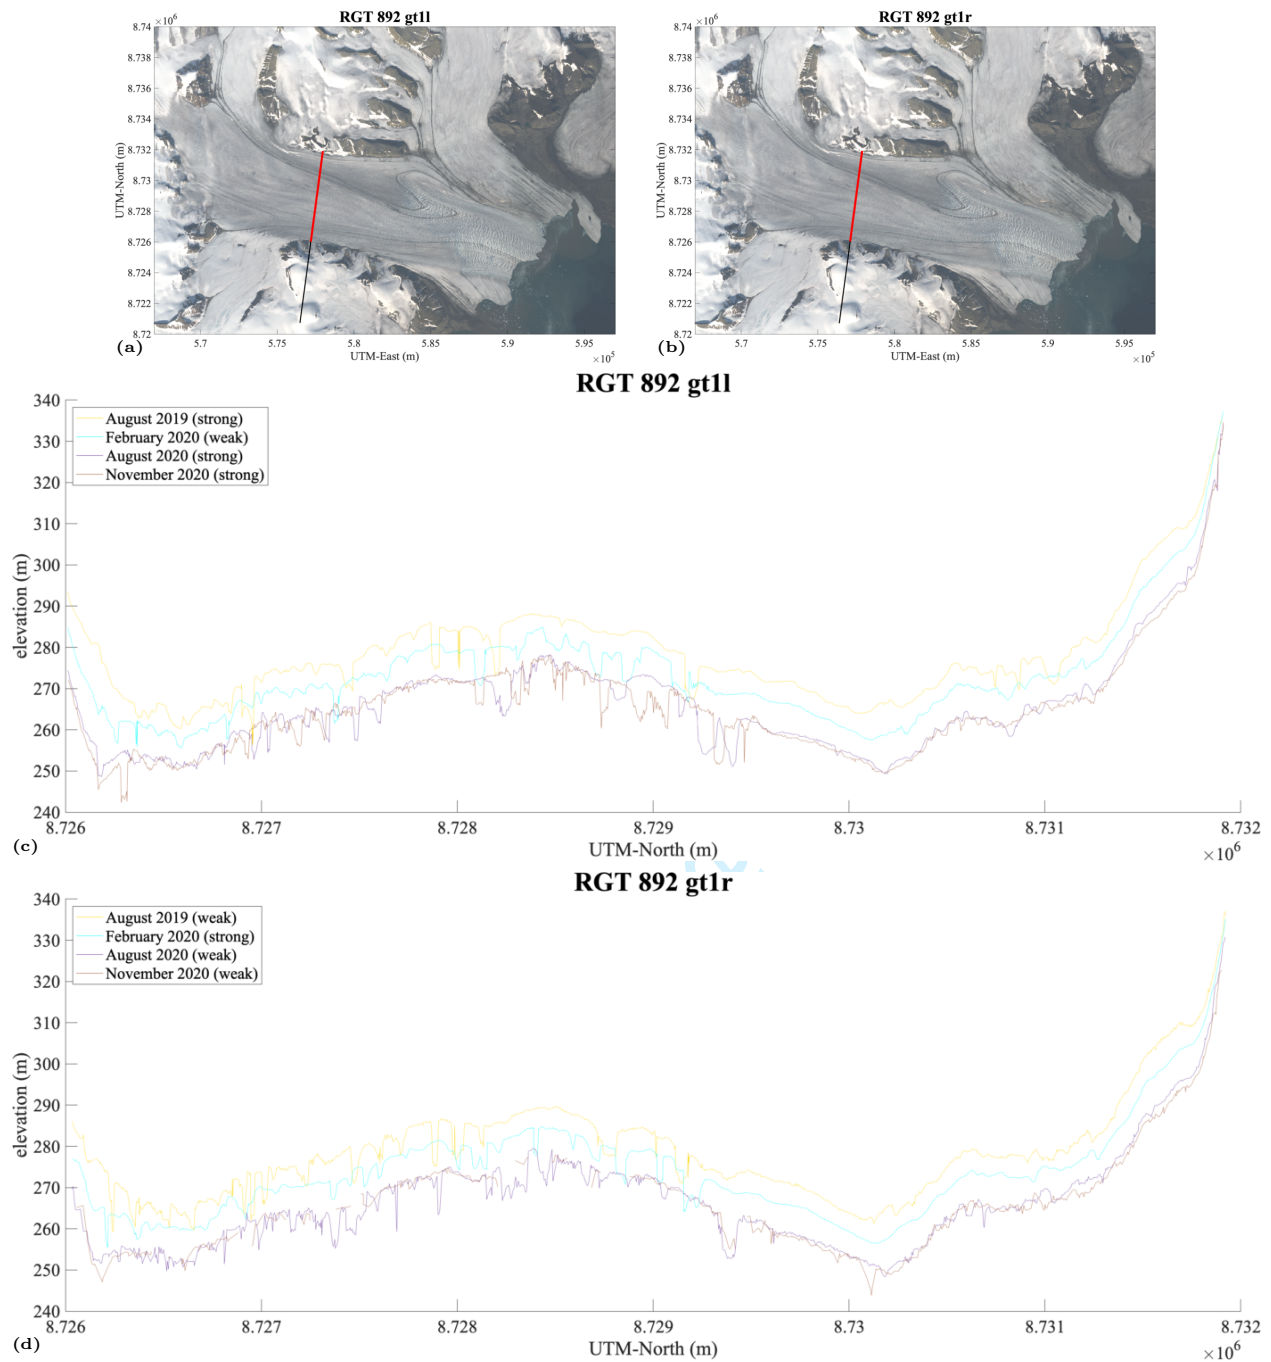

Figure 17: ICESat-2/DDA-ice surface height time series for RGT 892 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 892 gt1l segment over Negribreen, (b) Location of RGT 892 gt1r segment over Negribreen, (c) surface height time series of RGT 892 gt1l, and (d) surface height time series of RGT 892 gt1r.

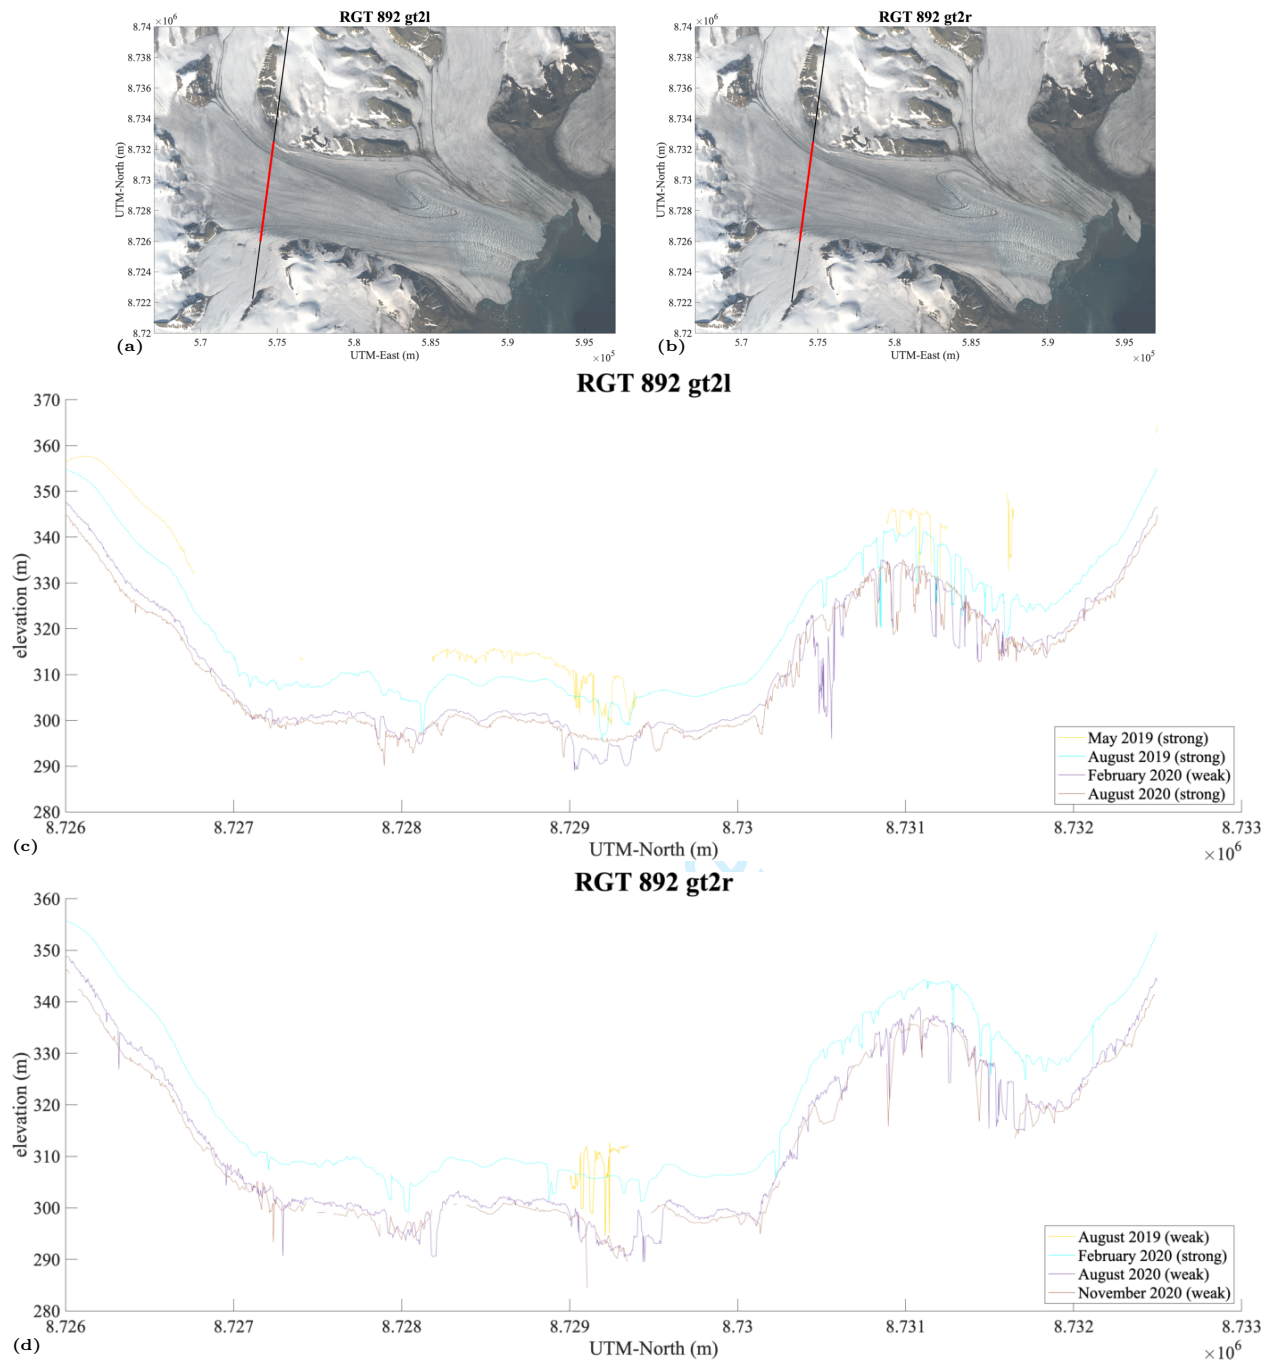

Figure 18: ICESat-2/DDA-ice surface height time series for RGT 892 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 892 gt2l segment over Negribreen, (b) Location of RGT 892 gt2r segment over Negribreen, (c) surface height time series of RGT 892 gt2l, and (d) surface height time series of RGT 892 gt2r.

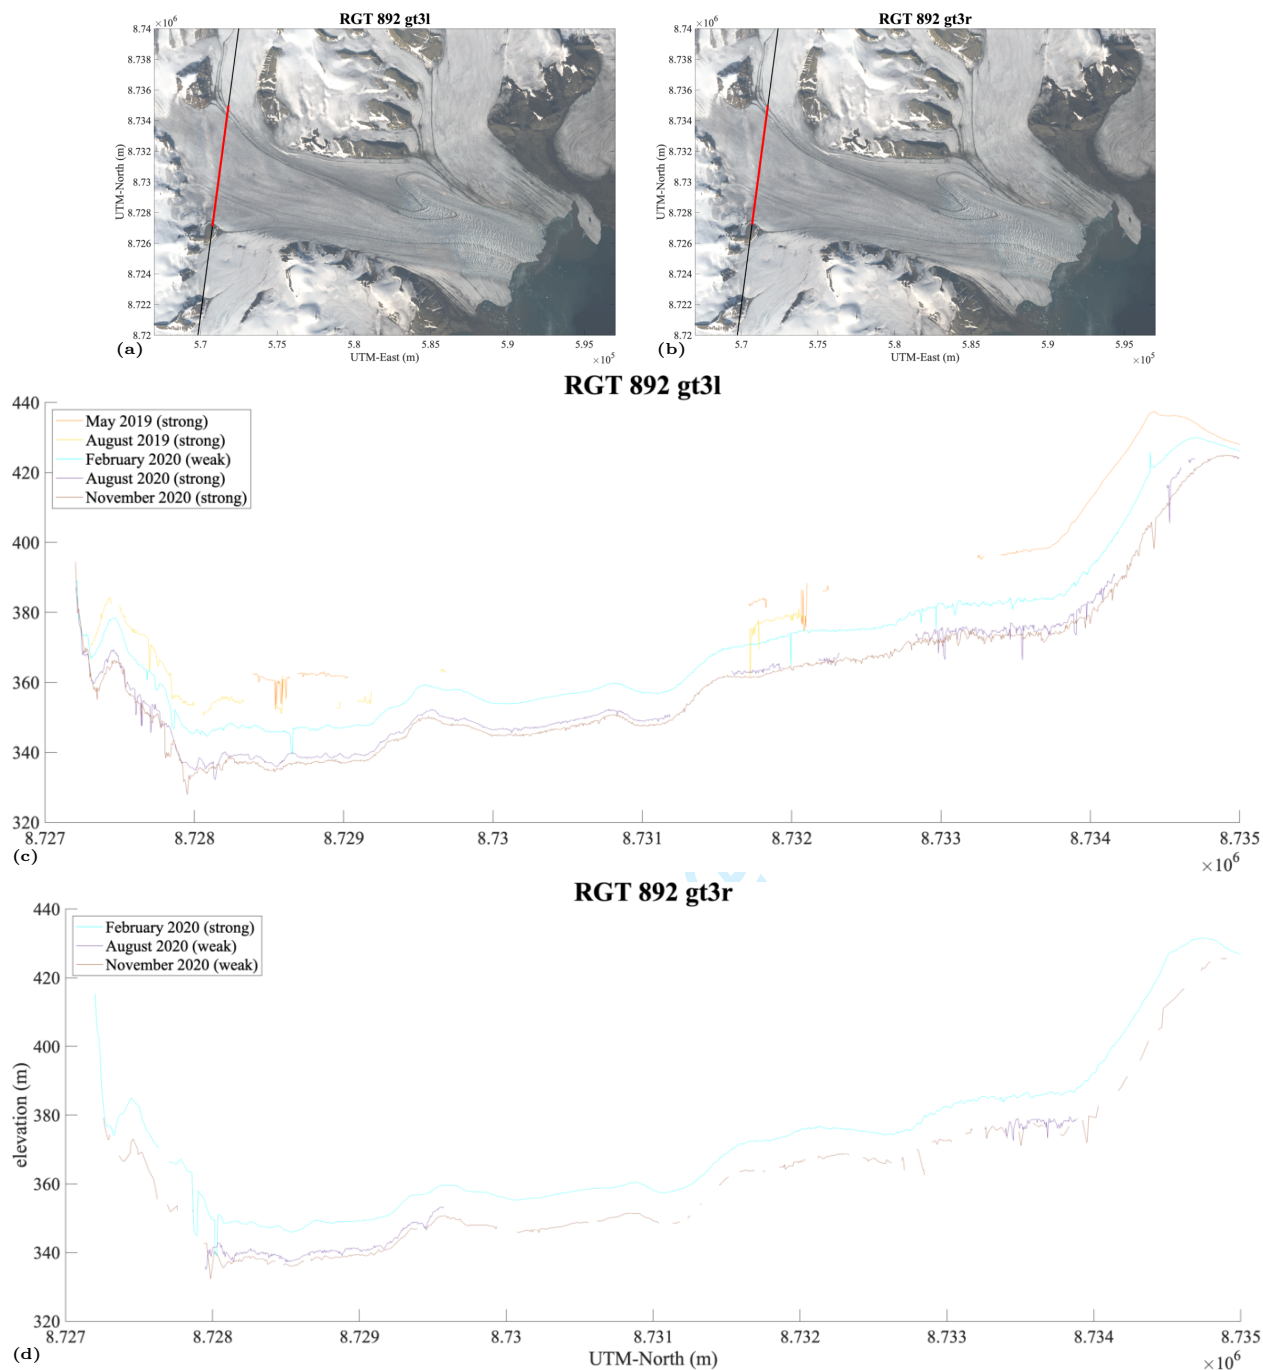

Figure 19: ICESat-2/DDA-ice surface height time series for RGT 892 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 892 gt3l segment over Negribreen, (b) Location of RGT 892 gt3r segment over Negribreen, (c) surface height time series of RGT 892 gt3l, and (d) surface height time series of RGT 892 gt3r.

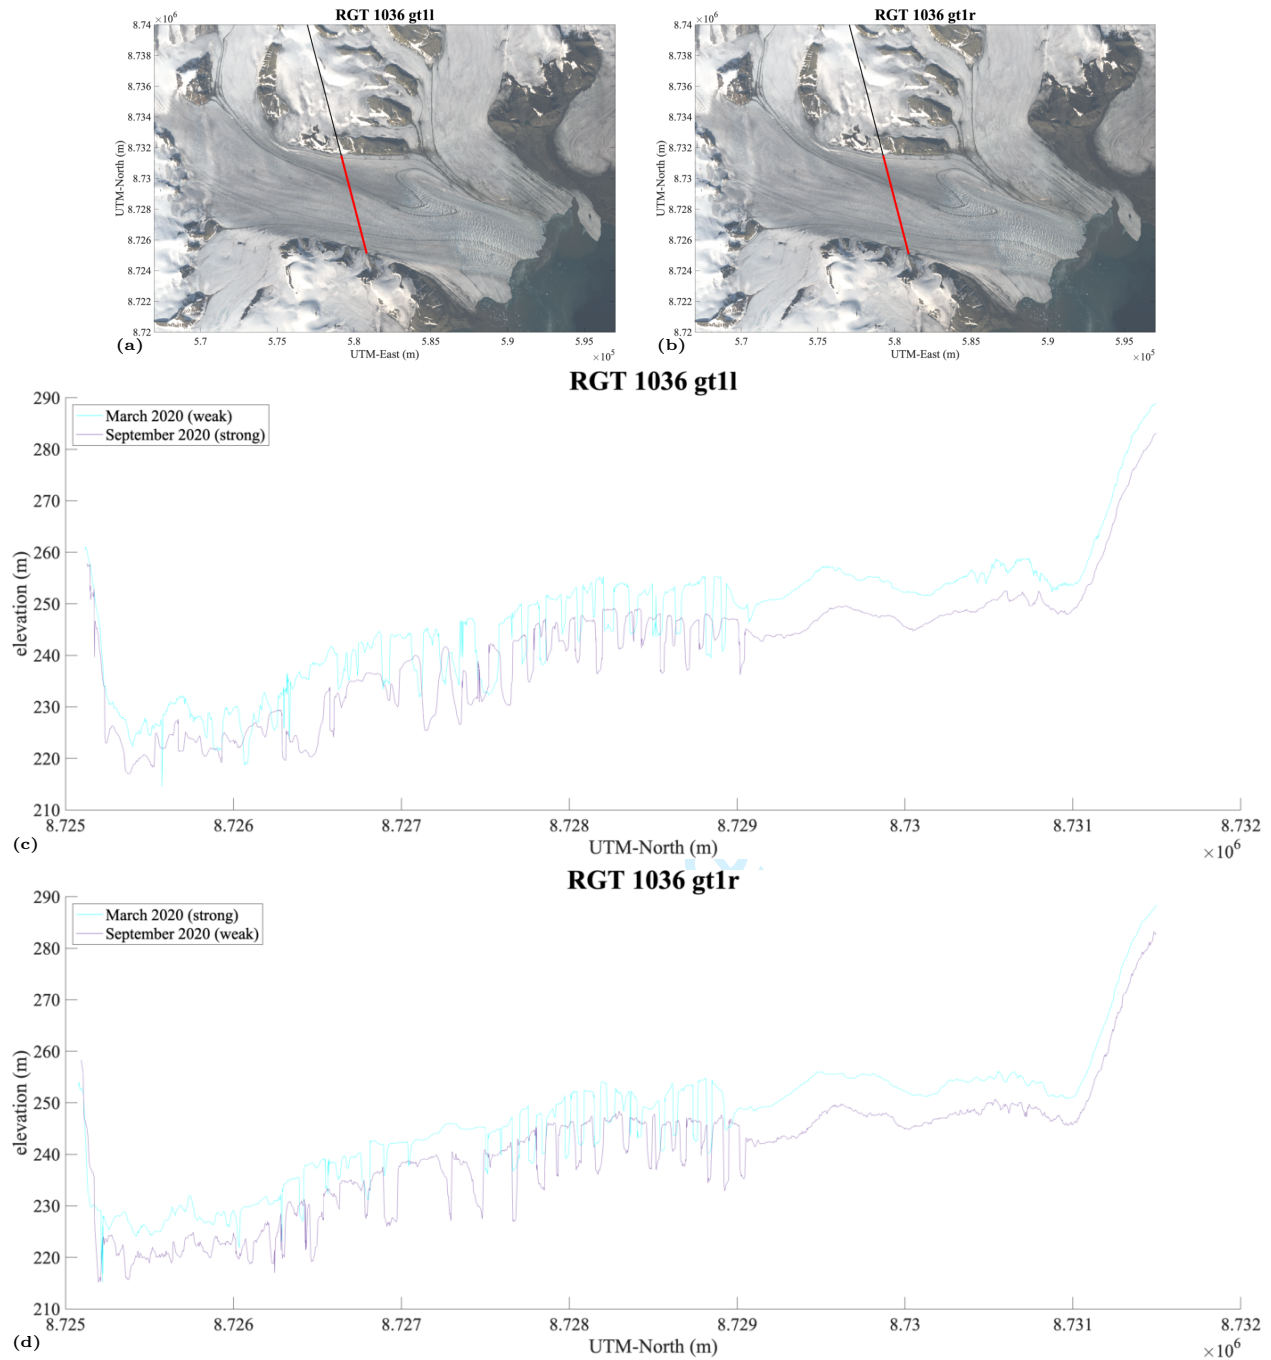

Figure 20: ICESat-2/DDA-ice surface height time series for RGT 1036 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 1036 gt1l segment over Negribreen, (b) Location of RGT 1036 gt1r segment over Negribreen, (c) surface height time series of RGT 1036 gt1l, and (d) surface height time series of RGT 1036 gt1r.

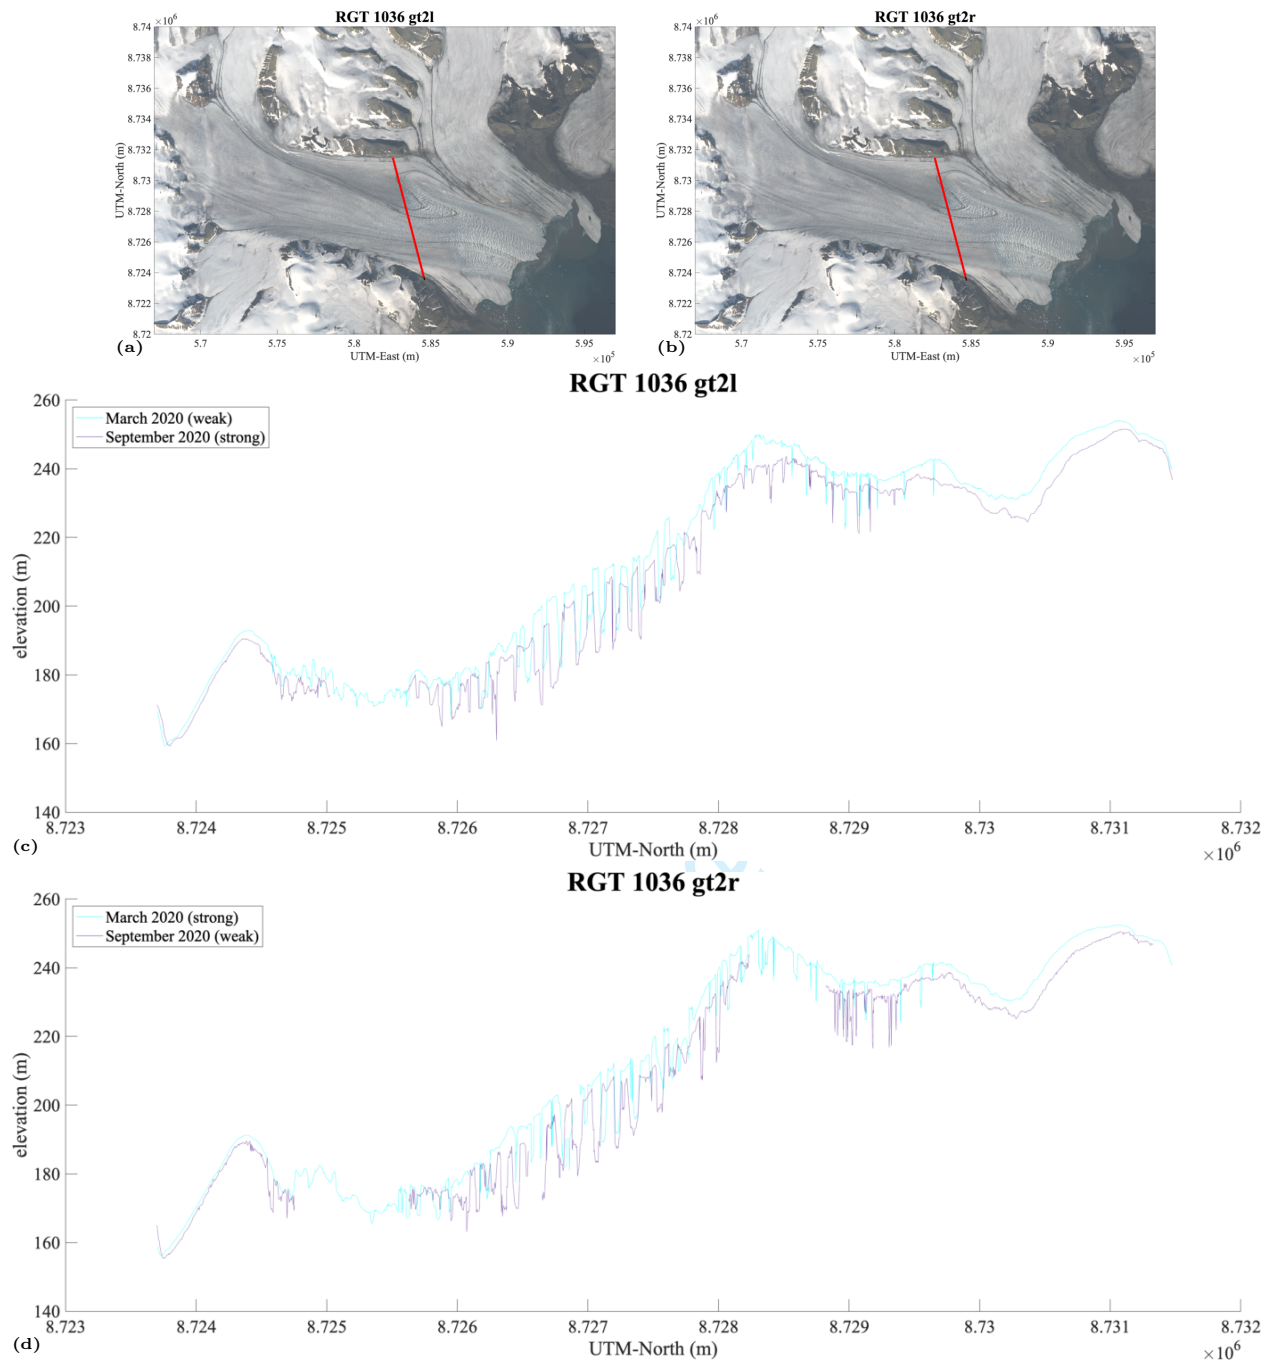

Figure 21: ICESat-2/DDA-ice surface height time series for RGT 1036 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 1036 gt2l segment over Negribreen, (b) Location of RGT 1036 gt2r segment over Negribreen, (c) surface height time series of RGT 1036 gt2l, and (d) surface height time series of RGT 1036 gt2r.

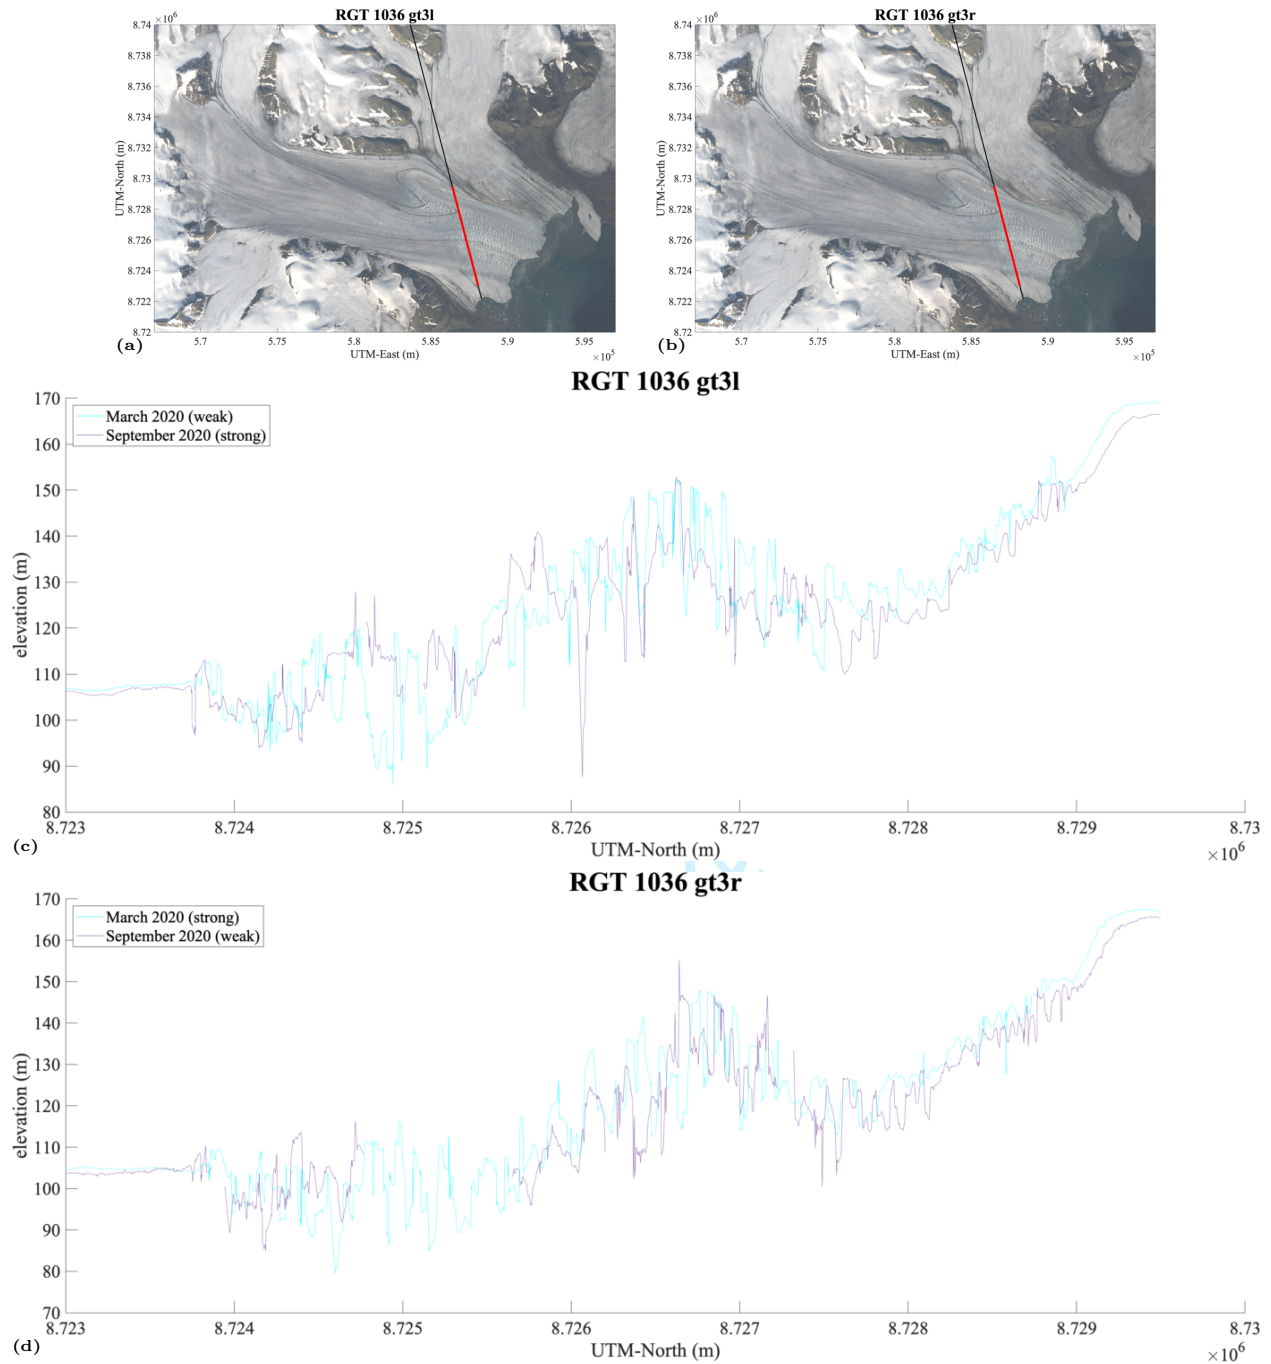

Figure 22: ICESat-2/DDA-ice surface height time series for RGT 1036 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 1036 gt3l segment over Negribreen, (b) Location of RGT 1036 gt3r segment over Negribreen, (c) surface height time series of RGT 1036 gt3l, and (d) surface height time series of RGT 1036 gt3r.

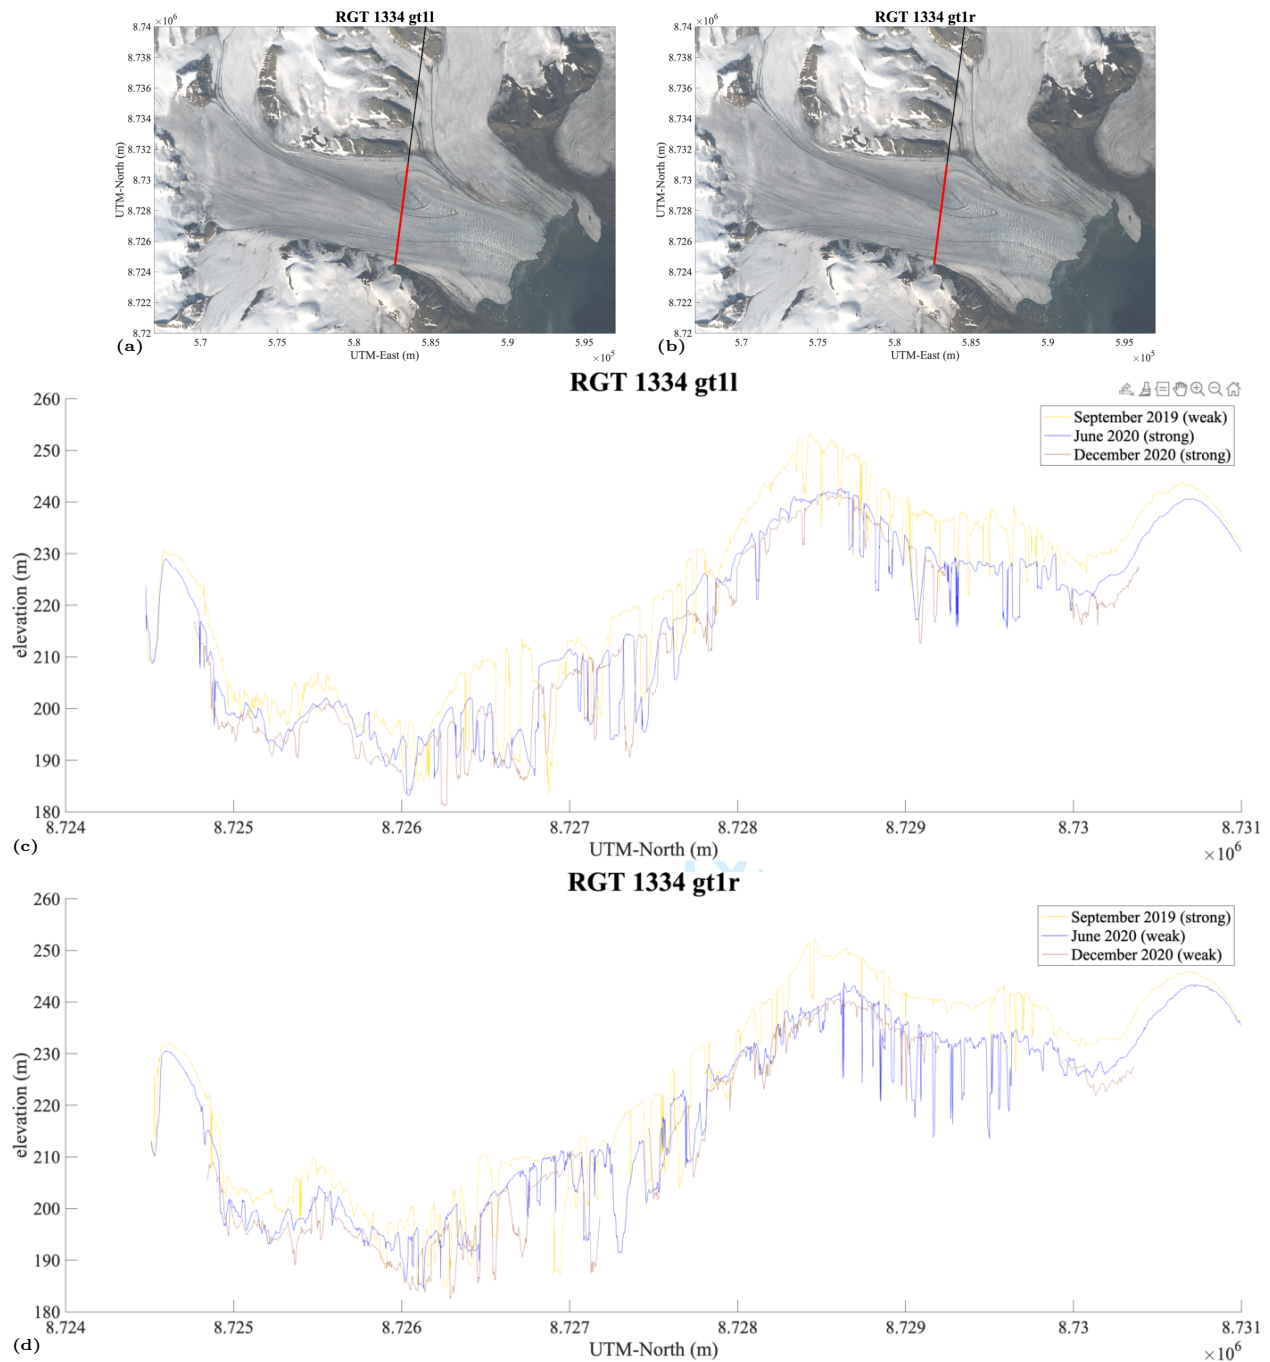

Figure 23: ICESat-2/DDA-ice surface height time series for RGT 1334 beam pair 1 over Negribreen, 2019-2020. (a) Location of RGT 1334 gt1l segment over Negribreen, (b) Location of RGT 1334 gt1r segment over Negribreen, (c) surface height time series of RGT 1334 gt1l, and (d) surface height time series of RGT 1334 gt1r.

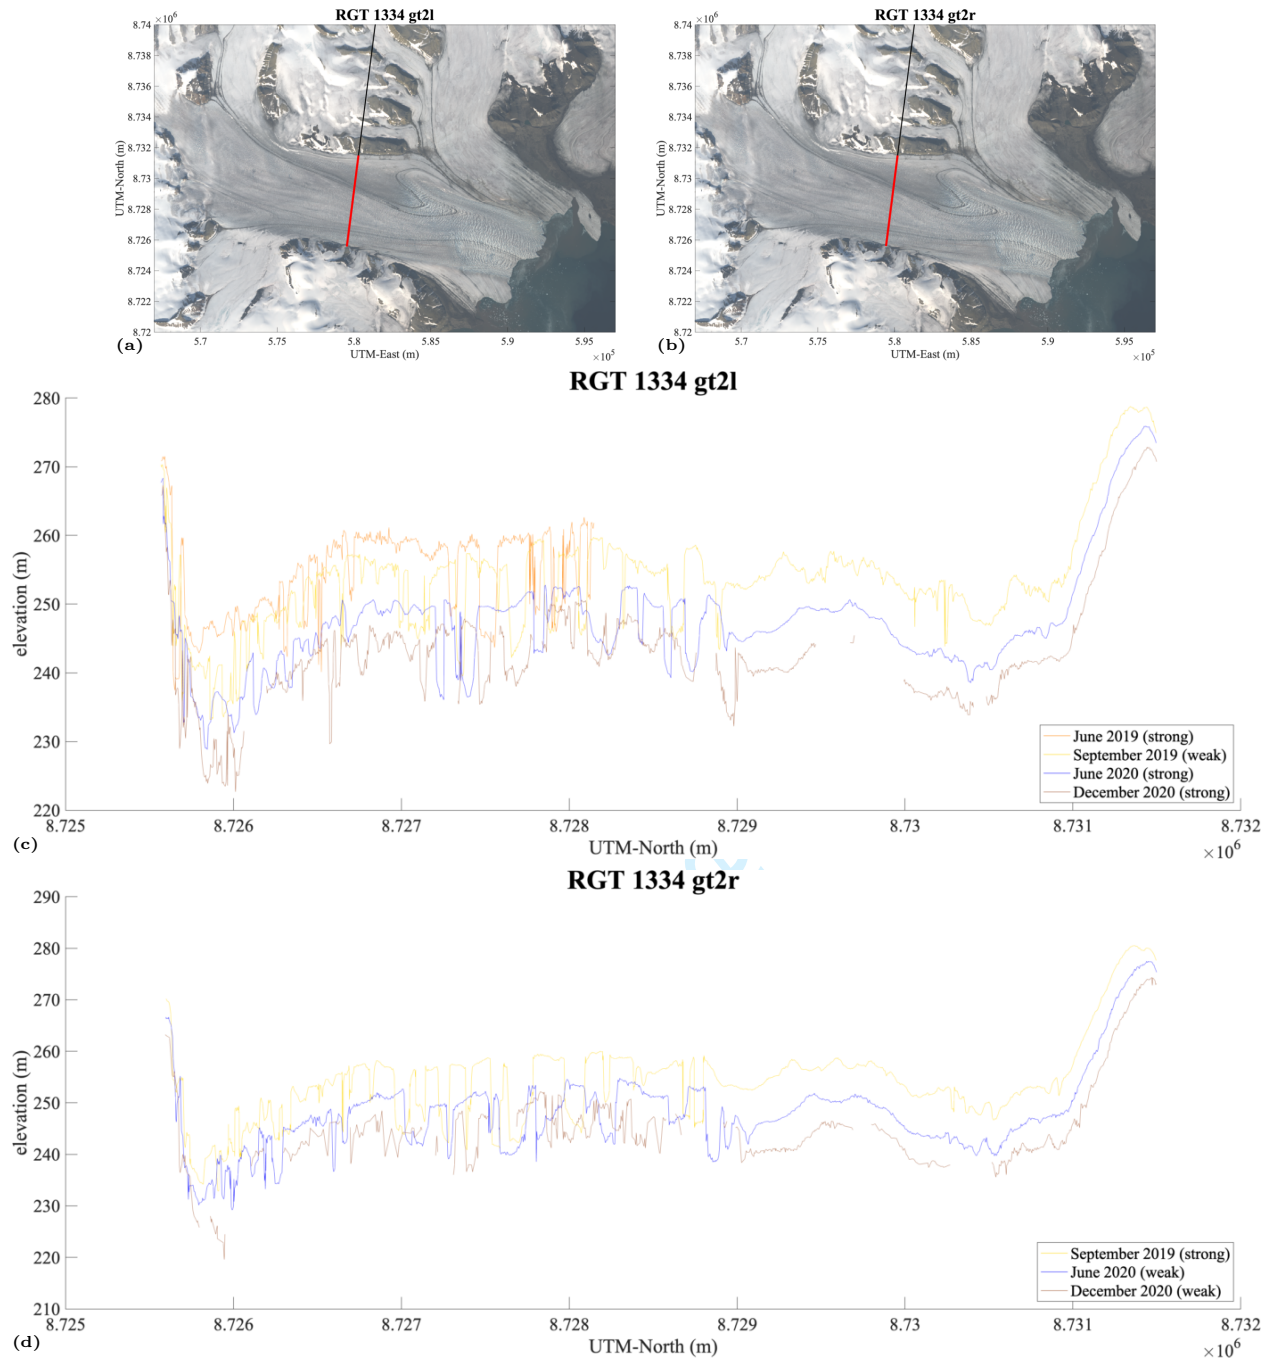

Figure 24: ICESat-2/DDA-ice surface height time series for RGT 1334 beam pair 2 over Negribreen, 2019-2020. (a) Location of RGT 1334 gt2l segment over Negribreen, (b) Location of RGT 1334 gt2r segment over Negribreen, (c) surface height time series of RGT 1334 gt2l, and (d) surface height time series of RGT 1334 gt2r.

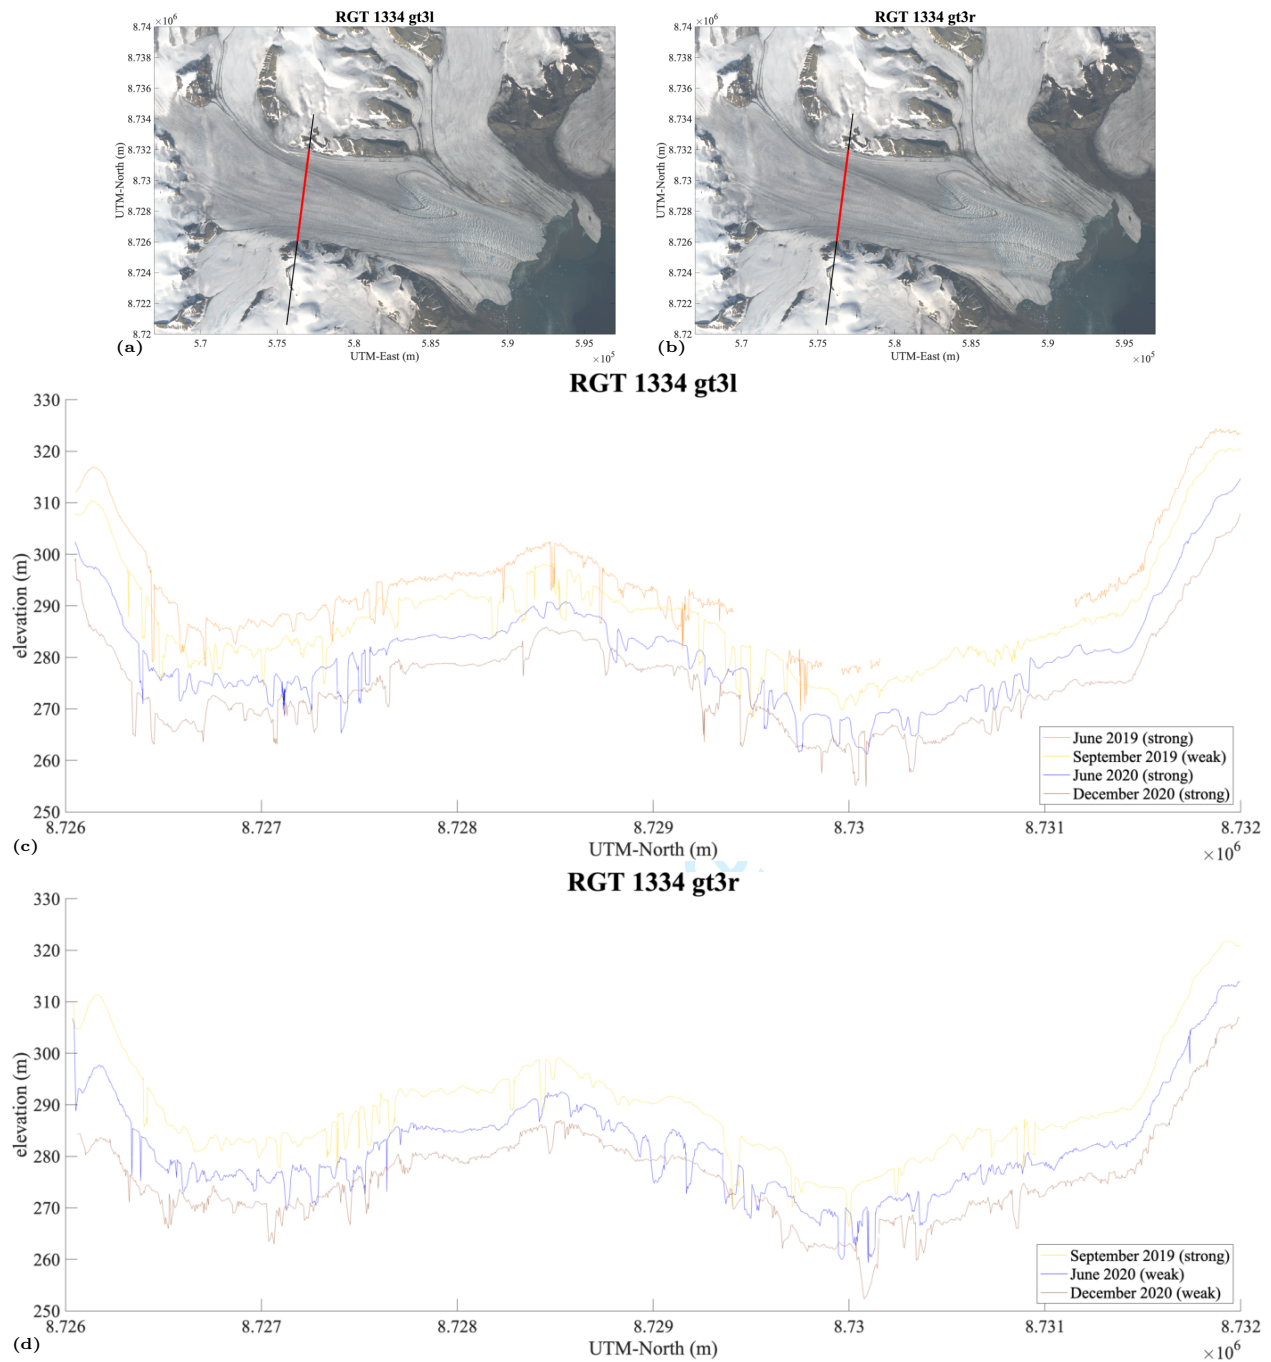

Figure 25: ICESat-2/DDA-ice surface height time series for RGT 1334 beam pair 3 over Negribreen, 2019-2020. (a) Location of RGT 1334 gt3l segment over Negribreen, (b) Location of RGT 1334 gt3r segment over Negribreen, (c) surface height time series of RGT 1334 gt3l, and (d) surface height time series of RGT 1334 gt3r.
