27

28 **Abstract**

29

30 Insurers and risk managers for critical infrastructure such as transport or power networks typically do not
31 account for flooding and extreme winds happening at the same time in their quantitative risk assessments. We
32 explore this potentially critical underestimation of risk from these co-occurring hazards through studying
33 events using the regional 12 km resolution UK Climate Projections for a 1981-1999 baseline and projections of
34 2061-2079 (RCP8.5). We create a new wintertime (Oct-Mar) set of 3,427 wind events to match an existing set
35 of fluvial flow extremes and design innovative multi-event *episodes* (Δt of 1-180 days long) that reflect how
36 periods of adverse weather affect society (e.g. through damage). We show that the probability of co-occurring
37 wind-flow episodes in Great Britain (GB) is underestimated 2-4 times if events are assumed independent.
38 Significantly, this underestimation is greater both as severity increases and episode length reduces, highlighting
39 the importance of considering risk from closely consecutive storms ($\Delta t \sim 3$ days) and the most severe storms. In
40 the future (2061-2079), joint wind-flow extremes are twice as likely as during 1981-1999. Statistical modelling
41 demonstrates that changes may significantly exceed thermodynamic expectations of higher river flows in a
42 wetter future climate. The largest co-occurrence increases happen in mid-winter (DJF) with changes in the
43 north Atlantic jet stream an important driver; we find the jet is strengthened and squeezed into a southward-
44 shifted latitude window (45-50°N) giving typical future conditions that match instances of high flows and joint
45 extremes impacting GB today. This strongly implies that the large-scale driving conditions (e.g. jet stream
46 state) for a multi-impact 'perfect storm' will vary by country; understanding regional drivers of weather hazards
47 over climate timescales is vital to inform risk mitigation and planning (e.g. diversification and mutual aid across
48 Europe).

53

54 **1. Introduction**

55

56 The challenge of multi-hazard risk has long been recognised for many natural hazards (Gallina et al., 2016;
57 Hillier, 2017; Kappes et al., 2012; UNEP, 1992; Ward et al., 2022) and storms in particular (e.g., Southern, 1979;
58 White, 1974). This co-occurrence of hazards has also recently been framed as 'compound events' (e.g.,
59 Simpson et al., 2021; Zscheischler et al., 2018). The difficulty is that the risk of impacts occurring together is
60 harder to quantify, whilst the impact of a combined event to society can be greater than would be the case if
61 the events were to occur separately (e.g., Hillier et al., 2023).

62

63 Inland flooding and extreme winds events cause the largest losses of the weather related hazards affecting
64 North-West Europe (European Environment Agency, 2024; Mitchell-Wallace et al., 2017; PERILS: Losses, 2024).
65 Illustratively, during 16th-21st February 2022 three storms (Dudley, Eunice and Franklin) inflicted various hazards
66 including flooding and extreme winds across the UK and Northwest Europe (Mühr et al., 2022; Volonté et al.,
67 2024a, b), resulting in multi-sector impacts (e.g. to transport and power distribution) and nearly €4 billion in
68 insured losses (Kendon, 2022; PERILS, 2023; Saville, 2022). Similarly, from 3rd-27th Dec 1999 the storm
69 sequence of Anatol, Lothar, Martin caused ~€10 billion insured property damage alone in Belgium, Switzerland,
70 Luxembourg, France, Germany, and Denmark (PERILS: Losses, 2024; Roberts et al., 2014).

71
72 Strikingly, most of the 98 impactful wintertime (Oct-March) wind or flood incidents in the PERILS database
73 (PERILS: Losses, 2024) from 2010 to 2024 affect Great Britain (GB, 73), more than France or Germany (38 or 47,
74 respectively). Moreover, wintertime correlation of proxies for flooding and extreme wind in countries near GB
75 appears similar (Bloomfield et al., 2023; Hillier and Dixon, 2020). This is likely because extra-tropical cyclones
76 typically track eastwards from the Atlantic (e.g., Roberts et al., 2014) and are a key driver of both hazards
77 across NW Europe (Fig. 1), illustrated by joint wind-flood events during named storms (e.g., Fink et al., 2009;
78 Kendon and McCarthy, 2015; Liberato, 2014; Matthews et al., 2018). As such GB is a useful sentinel location for
79 studying co-occurring flood-wind impacts in NW Europe.

89

90 Building on initial work establishing a relationship between flooding and extreme winds (Hillier et al., 2015;
91 Matthews et al., 2014), there is now strong evidence of co-occurrence in GB on daily to seasonal timescales
92 (Bloomfield et al., 2023; De Luca et al., 2017; Hillier and Dixon, 2020; Jones et al., 2024; Martius et al., 2016;
93 Owen et al., 2021b, a), perhaps controlled by the jet stream's characteristics via its influence on cyclogenesis
94 and storm evolution (Hillier and Dixon, 2020). Existing work predominantly uses heavy precipitation as a proxy
95 for flooding (e.g., Vignotto et al., 2021). As reviewed in Bloomfield et al (2023) studies using observed river
96 flow or impact data, which more directly relate to flooding, are much less common in GB (De Luca et al., 2017;
97 Hillier et al., 2015, 2020) or elsewhere (Küpfer, 2024). Indeed, even globally and considering modelled data,
98 work is sparse; only three studies assess the dependency of river flow and wind derived from the same
99 underlying climate model, two in GB (Bloomfield et al., 2023, 2024) and one globally for tropical cyclones
100 (Stalhandske et al., 2024). Thus, future change in joint wintertime flood-wind risk remains of interest.

101

102 Two recent studies have used the UK Climate Projections to advance understanding of the drivers of the
103 wintertime co-occurrence of potential flooding and extreme wind in GB, present and future. Bloomfield et al
104 (2024) used 30 pre-defined weather patterns from the 12 km horizontal resolution regional simulations of this
105 model (hereafter UKCP18r) and a GB hydrological model to assess the meteorological drivers of joint
106 wintertime wind and high flow extremes. For 1-day windows, using population-weighted severity indices, they
107 found cyclonic weather types typical, and also confirmed the positive phase of the North Atlantic Oscillation
108 (NAO+) as an associated state (Hillier et al., 2020). At seasonal timescales Bloomfield et al (2024) also
109 demonstrated a future increase in years that will be both wet and windy ($c. \times 3, p < 0.05$). Manning et al (2024)
110 used the convection permitting UKCP local (2.2 km horizontal resolution) to investigate the role of storm track
111 position and jet stream on the co-occurrence of wind and rain extremes. For individual storm events in mid-
112 winter (December-February) they ascribed future change in co-occurrence to predominantly thermodynamic
113 causes (i.e. warmer and therefore wetter conditions) supported by a more southerly jet stream position during
114 those storms. Both papers find a 4-fold increase in short-duration joint events (i.e. ≤ 1 -day) into the future.

115

116 Our work here provides several unique contributions to this research area. Using high flows rather than
117 precipitation, it quantifies the co-occurrence of events (E) within multi-hazard *episodes* (ε) spanning daily to
118 seasonal durations (i.e. $\Delta t = 1$ -180 days long) from October to March in the UKCP18 regional data (1981-1999,
119 2061-2079). It uses high flows as they do not simply arise from precipitation in individual storms, so the
120 causative storm(s) might differ in character as might antecedent conditions (e.g. soil saturation) and associated
121 jet stream dynamics. It examines more deeply the role of the jet stream, primarily by investigating the role of
122 seasonality (i.e. the time-distribution of events within the winter). To do this it employs an accessible index
123 that is widely used to characterise the latitude and strength of the North Atlantic jet (Woollings et al., 2010),
124 which will enable future inter-comparison between climate models. Finally, to give real-world relevance it
125 develops an Event Coincidence Analysis approach using dynamically positioned time windows (dwECA) to

126 reflect how these multi-event windy episodes coincident with high river flows ($\Delta t = 1-180$ days) are
127 experienced societally.

128

129 To define distinct claims (re)insurers commonly use windows of 72 hours for storms ($\Delta t = 3$ days) or 21 days for
130 floods (so-called 'hours clauses' e.g., Mitchell-Wallace et al., 2017; PERILS, 2023), which insurers will position to
131 encompass the maximum loss possible. More widely, key impacts are typically documented (e.g. by an
132 emergency response manager) with a day-to-day description e.g. "*It started with the storm on Tuesday, and*
133 *ended after the last heavy rain on Sunday*". As such, our proposal of dynamic time windows for episodes (ε)
134 uses the weather events (E) themselves to define the evident start and end of the adverse conditions, as an
135 interested observer might. To study individual weather phenomena (e.g. distinct storm) a buffer approach has
136 been used, such as ± 24 h (i.e., Manning et al., 2024; Martius et al., 2016) to give a 3-day symmetrical window.
137 However, it is less straightforward to appropriately capture an episode containing a cluster of storms over a
138 longer period such as 14-days (e.g., Vitolo et al., 2009), and non-overlapping windows or block maxima (e.g.,
139 Bloomfield et al., 2023; Zscheischler et al., 2021) may chop a storm in half. Also, time-to-peak modelling of
140 hydrographs indicates that riverine responses to precipitation in GB are $\lesssim 40$ h (De Luca et al., 2017), giving a
141 lag *after* a storm that should be accounted for. So, as well as aligning with timescales associated with storms,
142 our analysis is designed to align with stakeholder definitions and experience, with insurers providing a specific
143 motivation to focus on time windows (Δt) of 3 and 21 days. The work has real-world relevance as even in
144 insurance, where natural hazard risk modelling is quite mature (e.g., Mitchell-Wallace et al., 2017) because
145 flooding and extreme wind models of NW Europe are still independently derived; they are based on different
146 underlying climate simulations (Dixon et al., 2017; Hillier et al., 2024), with potentially significant
147 underestimates of financial losses (Hillier et al 2023, 2024).

148

149 Using the idea of framing multi-hazard risk environments as an in-depth or user focussed case study to cut
150 through complexity (Hillier and Van Meeteren, 2024; Ward et al., 2022) the present work is framed by the
151 insurance sector, yet results are more widely applicable across society, answering four main research
152 questions:

153

- 154 1. To what extent do the most severe extreme winds and flows tend to co-occur? Particularly, asymptotic
155 dependence is considered.
- 156 2. How does strength of co-occurrence vary with the time-window (Δt) used to group events into
157 episodes?
- 158 3. How effectively might relatively simple metrics of jet position and strength be used in a functional,
159 readily applied tool to distinguish jet states characteristic of co-occurrence?

160 4. How do future changes in the North Atlantic jet stream influence co-occurrence in climate model
161 simulations of the future?
162

163 2. Data & Methods

164

165 The workflow in Fig. 2 is used to produce individual events for wind (E_W) and flood (E_F) with timestamps from
166 the same underlying climate model, namely the UKCP18 12 km, RCP8.5 perturbed parameter ensemble,
167 hereafter UKCP18r. Then, from these ensemble members, multi-hazard *episodes* (ϵ) are created and analysed.
168 All metrics are calculated during extended winter (October–March) and nationally aggregated. Thresholds are
169 defined from the present-day climate simulations, with values of event severity metrics assigned in absolute
170 terms based on each percentile used, with these 1981-1999 absolute values then applied to future climate to
171 understand potential changes.
172

173 Existing data and practice (e.g. thresholds, definitions) are adopted to create events and define their severity
174 (Bloomfield et al., 2023; Griffin et al., 2022a, b; Manning et al., 2024), with a detailed justification of this choice
175 given in Appendix A which updates these discussions to include the latest literature. Importantly, the co-
176 occurrence of events for the simulated present (1981-1999) in UKCP18r replicates well that in historic
177 observations. Respective Spearman’s rank correlations between GB aggregated high river flows and extreme
178 wind, calculated for time windows ranging from 1 to 180 days in UKCP18r and observations, match closely. This
179 holds true even when taking multiple historic weather datasets and river-flows derived from them (Bloomfield
180 et al., 2023, 2024; Harrigan et al., 2023; Hersbach et al., 2020; Hirpa et al., 2018). Indeed, these correlations
181 have also been verified against impacts on the GB rail network (Bloomfield et al., 2023). UKCP18r simulations
182 therefore appear to adequately capture the level of co-occurrence between extreme winds and high river flows
183 (detail in Appendix A.1).
184

185 2.1. Defining events (E) for each separate hazard

186

187 Each event (E) is a grid of the maxima of a hazard driver (e.g. v) during a time-window containing an isolated
188 hydro-meteorological extreme (detail in Appendix A.2). For each event, summary metrics (total area, duration,
189 severity index) are assigned to a single date t_{max} , the individual day during the event when the greatest
190 number of grid cells exceeding the set threshold level for that hazard driver. An event’s Storm Severity Index,
191 $SSI(E)$ follows Klawa and Ulrich (2003) as given by Eq. (1) and Table 1, with this choice of SSI form and hazard
192 percentile threshold supported by a literature review updated to include the latest work in Appendix A.3:
193

194 Eq. (1)

$$SSI(E) = \sum_{i=1}^{N_i} \sum_{j=1}^{N_j} \left(\frac{v(E)_{i,j}}{v_{i,j}^{98}} - 1 \right)^3 \cdot I_{i,j}$$

195

$$I_{i,j} = \begin{cases} 0 & \text{if } v(E)_{i,j} < v_{i,j}^{98} \\ 1 & \text{otherwise} \end{cases}$$

196

197 *Table 1: Table of parameters used, with precipitation included for completeness (see Appendix A).*

Parameter	Symbol	Units
Maximum daily 10 m wind gusts at a grid cell i,j , and the threshold (98 th) percentile taken to define extreme at a grid cell.	$v, v_{i,j}, v^{98}$	ms^{-1}
Total daily precipitation, and the threshold (98 th) percentile taken to define extreme at a grid cell.	$p, p_{i,j}, p^{98}$	mm
Daily mean river flow.	$q, q_{i,j}, q^{99.5}$	$m^3 s^{-1}$
Day	t	days
Event E . Type of event is W, F or P : W is for Wind, F is for river flows and P is precipitation. k is the event's identification number within the set.	$E_{W,k}$	-
Multi-hazard episode ε , with its type (wind W , high flow F , joint J) and severity percentile exceeded by the episode's constituent events (i.e. >75 th , 95 th or 99 th of events within the relevant event set). Also see Fig. 3.	ε_W^{95}	-
Event's most extreme day, to which summary statistics (e.g. duration, FSI) are assigned.	t_{max}	days
Temporal limits of an event (i.e. start and end)	t_{start}, t_{end}	days
Length of multi-hazard episode, 'time window'	Δt	days

198

199

200 For simplicity, and to avoid a judgement linking value directly to population density (e.g. consider a wind farm),
 201 no population weighting is used. The optimal formulation of SSI (e.g. power-law, exponential, wind threshold,
 202 storm duration) is still actively debated. Most pertinently, probabilistic models that account for the uncertainty
 203 in how individual assets are damaged (Heneka et al., 2006; Heneka and Ruck, 2008; Pardowitz et al., 2016;
 204 Prah et al., 2012) better approximate losses in Germany across all 2004 wintertime days in 11 years (1997-
 205 2007). The exception to this is the costliest days (~10 per year), which are still adequately modelled using cubic
 206 excess-over-threshold approach with a 98th percentile (Prah et al., 2015). Thus, using Eq. (1) is appropriate
 207 here. Because recent developments have not been previously reviewed, a detailed justification is in Appendix
 208 A.3. The new wind event set is described in Appendix A.4.

209

210 Based on the form of SSI, Flood Severity Indices (FSI) have recently been developed (Bloomfield et al., 2023).

211

212

Only grid cells on the river network are used, again with no population weighting. Thus, each events' flood severity $FSI(E)$ is given by Eq. 2 and Table 1 with the 99.5th percentile choice based on previous sensitivity

213 testing and verifications (Bloomfield et al., 2023; Griffin et al., 2022a, b); see Appendix A. 2 for a detailed
 214 justification.

215

216 Eq. (2)
$$FSI(E) = \sum_{i=1}^{N_i} \sum_{j=1}^{N_j} \left(\frac{q(E)_{i,j}}{q_{i,j}^{99.5}} - 1 \right) \cdot I_{i,j}$$

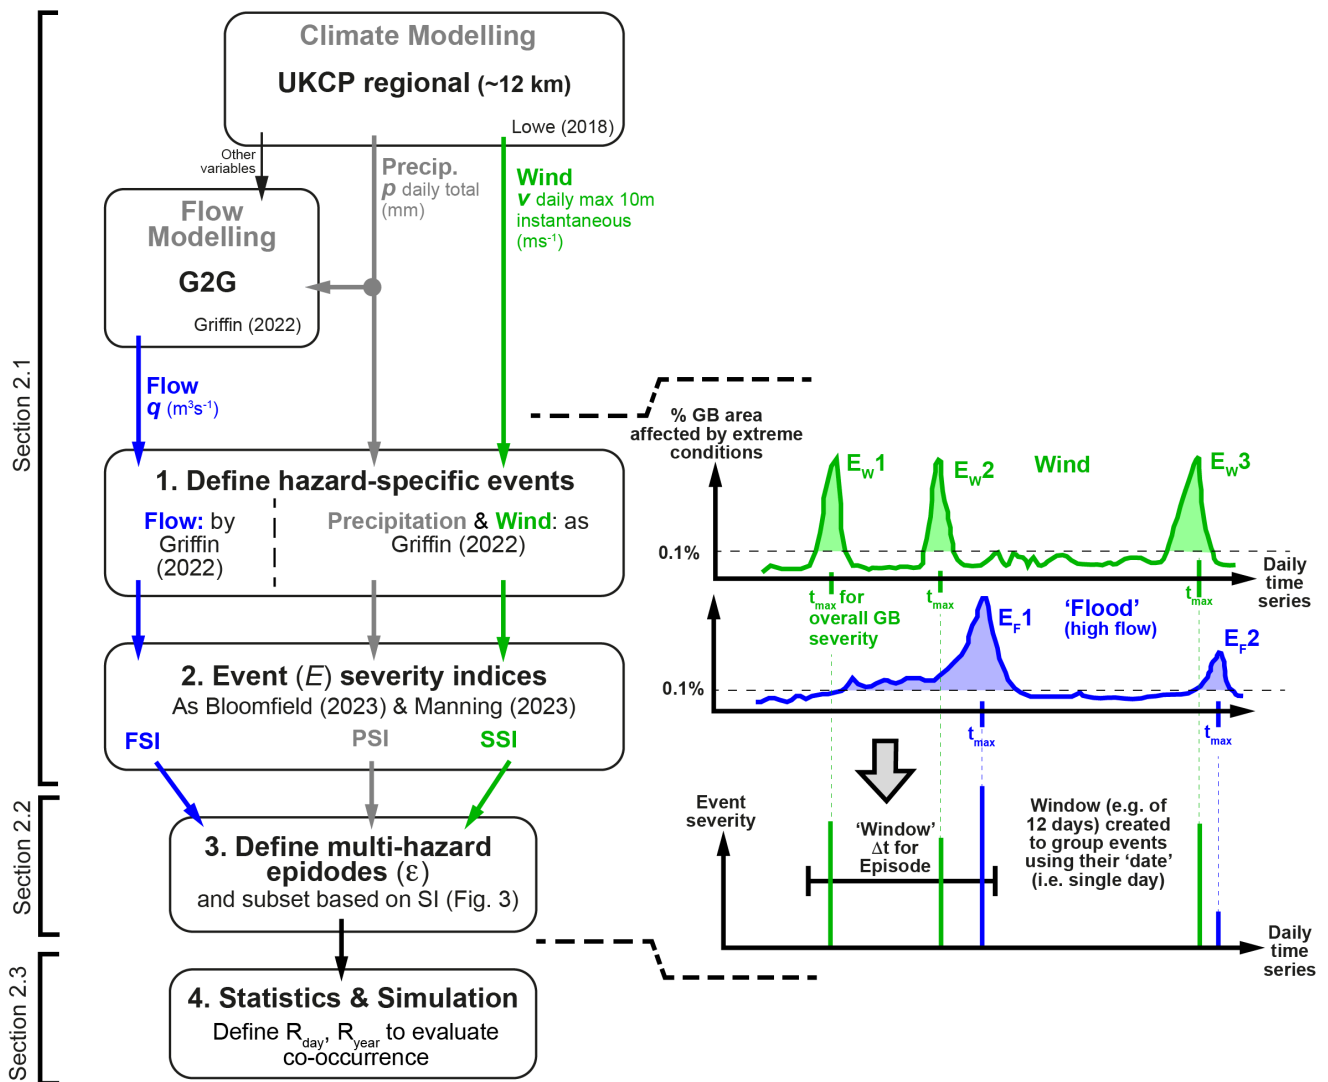

217

$$I_{i,j} = \begin{cases} 0 & \text{if } q(E)_{i,j} < q_{i,j}^{99.5} \\ 1 & \text{otherwise} \end{cases}$$

218

219 Debate on the form of FSI is expected to continue, so a detailed justification is in Appendix A.3. Pertinently, FSI
 220 as configured in Eq. 2 is suitable here as only extreme and potentially damaging events are later selected for
 221 analysis, namely those exceeding at least the 75th percentile of events (see Fig. 3); using the 75th percentile for
 222 this selection gives 5-6 high flows per year, comparable to the ~7 floods per year in commercial risk models
 223 (Hillier et al., 2024). The threshold used depends on the time window Δt as explained below, and sensitivity
 224 testing has been conducted to examine the impact of these choices (Fig. 5).

225

226

227 Fig. 2: Workflow used in this analysis, including definitions for some of the variables. Detailed explanation is in main text. For the flow
228 data from Grid-to-Grid (G2G) (Griffin et al., 2022a), 0.1% of the river network is ~ 20 cells, or $> \sim 20$ km². For the UKCP18r data on wind
229 gusts and precipitation 0.1% is of the GB land area is ≥ 2 cells or ~ 300 km². To find the largest SI to create episodes, FSI and SSI are
230 normalized so that their 95th percentile values are equal (ratio = 1.0). In reality, rare storms might have twice the impact of floods (e.g.,
231 Hillier et al., 2024), but sensitivity testing shows that ratios of 0.5 and 2.0 have minimal effect on the episodes defined. Time series are
232 illustrative, not real data. Precipitation is included for completeness (see Appendix A).

233

234 2.2. Defining multi-hazard episodes (ϵ)

235

236 Extratropical cyclones cluster in time, with 2 or 3 meteorologically distinct cyclonic systems (Mailier et al.,
237 2006; Vitolo et al., 2009) combining in longer windy periods. Similarly, rainy days occurring in succession might
238 be grouped in episodes (Kopp et al., 2021). Here, this concept is applied to multi-hazards (Fig. 2), adopting the
239 term *episode* (ϵ) and applying it to mean a grouping in time of hazardous events (E) within a selected spatial
240 domain as is established practice when hazards co-occur (e.g., Bloomfield et al., 2023; De Luca et al., 2017;
241 Hewitt and Burton, 1971; Hillier et al., 2015; Kappes et al., 2012). In this case the domain is set to GB. The
242 temporal grouping approach accounts for a time-lag between events as do Claassen et al. (2023), but the
243 protocols differ in that here they are stakeholder rather than hazard driven. In particular the time-lag here
244 might also be due to impact related factors (e.g. time to develop, repair or recovery time, staff fatigue, an
245 organisation's reporting timeframe, an April-March financial year) not just duration and overlap of physical
246 hazard (e.g., Hillier et al., 2023; Hillier and Dixon, 2020; de Ruiter et al., 2019).

247

248 Episodes are defined for a prescribed window length of Δt days, although the episode creation process can be
249 repeated later for other window lengths. For each Δt , episodes are defined by starting with the event with the
250 greatest severity index (SI), placing a window of length Δt days around it dynamically positioned so as to
251 capture other events that create the largest total SI (see Fig. 2), and then removing these events from the initial
252 list. Then, this is repeated until all events are accounted for. Once created, an episodes' severity at this Δt must
253 be quantified.

254

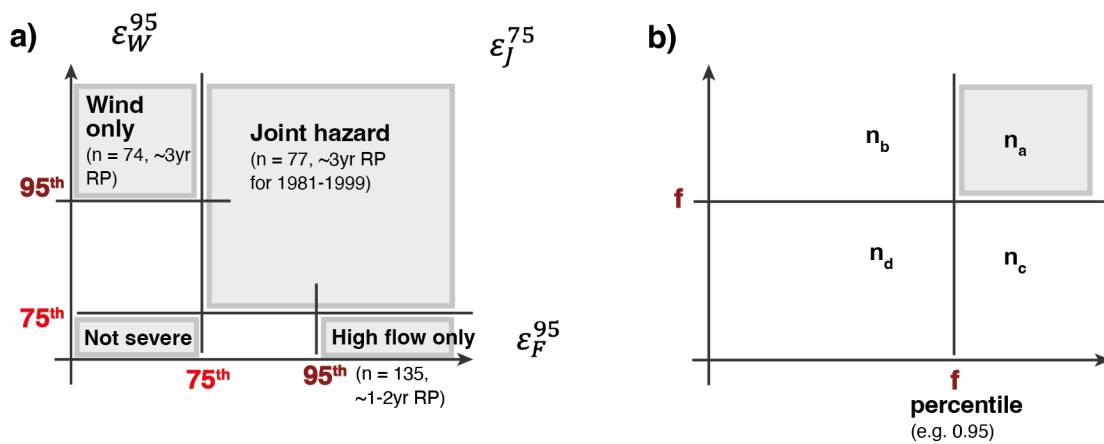

255 That flood-wind co-occurrence might be enhanced by a greater frequency of an NAO+ state across a 180-day
256 season (Bloomfield et al., 2024; Hillier et al., 2020) raises the technical question of how to quantify severity for
257 long episodes. This depends on stakeholder and purpose. It is possible to simply sum daily SSI or FSI
258 (Bloomfield et al., 2023), implicitly assuming that each day is independent and additive in its impact (i.e.
259 duration/persistence is significant). Is being flooded at 2.0m depth for 5 days five times more damaging than
260 for 1 day? For an electricity network operator fined by customer minutes lost, it might be (Wilkinson et al.,
261 2022). As the strongest gusts or highest river levels during an event approximate insured damage well
262 (Mitchell-Wallace et al., 2017), an alternative is to use an event-based approach (e.g., Griffin et al., 2022b;

263 Roberts et al., 2014), then sum events' losses. This implicitly assumes a reset between events, ignoring
 264 duration (Appendix A.3) and is the (re)insurance approach followed in Fig. 4.

265

266 Here, our main aim is to quantify the co-occurrence of large events that drive risk. So, episodes (ε) are
 267 classified by the severity of their constituent events (Table 1), with thresholds chosen to select potentially
 268 impactful events (Section 2.1, Appendix A.3) and mutually exclusive subsets containing roughly equal numbers
 269 of episodes (i.e. RPs). This classification is *not* a summation. Illustratively, ε_W^{95} contains at least one wind event
 270 E_W with an SSI in the top 5% of wind events but no high flow event. Fig. 3 shows the thresholds for $\Delta t = 3$ days.
 271 For $\Delta t = 21$ days, since longer windows can more readily unite rarer and more extreme events, joint hazard (ε_J)
 272 uses the 95th percentile and individual hazards ($\varepsilon_F, \varepsilon_W$) the 99th.

273

274

275 Fig. 3: a) Illustration of subsets and nomenclature used, with numerical detail for $\Delta t = 3$ during 1981-1999 from Fig. 4a. ε_J^{75} is the subset
 276 of all episodes with both hazards jointly having at least one event exceeding the 75th percentile. Also see Table 1. b) Nomenclature used
 277 to define U in Section 2.3: f is the percentile threshold defining episodes as large or potentially impactful, as a fraction; n is the total
 278 count of episodes, divided into subsets n_a to n_d depending upon whether or not they exceed the threshold for river flow on the x-axis
 279 and/or extreme wind on the y-axis.

280 2.3. Statistical simulation for co-occurrence analysis

281

282 A variety of options exist to quantify dependency of hydro-meteorological extremes (e.g., Bevacqua et al.,
 283 2021; Heffernan and Tawn, 2004; Serinaldi and Papalexiou, 2020), although it is advised to ensure that they
 284 are not reinvented or untested (Serinaldi et al., 2022). One well-established approach is using copulas to fit a
 285 distribution to data extreme in both variables (e.g., Bevacqua et al., 2017; Manning et al., 2024). This permits
 286 smoothed curves to be fitted, but relies upon selecting an appropriate distribution (e.g. Gumbel copula).
 287 Alternatively, extremal dependency for wet and windy conditions can be quantified by measures of the co-
 288 occurrence of extremes above a given percentile (Hillier et al., 2015; Martius et al., 2016; Owen et al., 2021a).
 289 χ (Coles et al., 1999) and uplift in co-occurrence U (De Luca et al., 2017; Hillier et al., 2015), which are closely
 290 related (Eq. 3, 4) with nomenclature as defined in Fig. 3b.

291

292 Eq.3

$$\chi = \frac{n_a}{(1-f)n}$$

293

294 Eq. 4

$$U = \frac{n_a}{E[n_a]} = \frac{n_a}{(1-f)^2 n}$$

295

296 χ is the probability that one variable is extreme if the other is also extreme, varying between 0 and 1 (e.g.,
297 Bloomfield et al., 2023; Vignotto et al., 2021). U is an occurrence ratio, the observed number of co-
298 occurrences divided by the number expected due to chance for independent events (i.e. $E[n_a]$). It is also,
299 therefore, the extent to which one would underestimate the probability of co-occurrence if independence
300 were assumed. Some authors have called U a ‘Likelihood multiplication factor’ (Ridder et al., 2020; Zscheischler
301 and Seneviratne, 2017). With independent events uniformly distributed over a time period, the significance of
302 U is found with a binomial test (Bevacqua et al., 2021), but $E[n_a]$ can also be simulated directly.

303

304 Event Coincidence Analysis (ECA) is a method in time-series analysis to assess if one type of event might be a
305 precursor to another based on an underlying Poisson process (e.g. netCoin or CoinCalc R packages) (Donges et
306 al., 2016; Escobar, 2015; Siegmund et al., 2017). With the dynamic positioning of the window and 1 to n
307 events potentially within each episode, it is not straightforward to construct this analytically. So, statistical
308 simulation modelling (e.g., Hillier et al., 2015; Ridder et al., 2020) is used to calculate $E[n_a]$ to investigate U in
309 UKCP18r by eliminating elements of its temporal structure (Hillier et al., 2015, 2020; Hillier and Dixon, 2020;
310 Zscheischler et al., 2021). For this simulation modelling an ECA is designed that uses dynamic windows to form
311 episodes, which we name here dwECA; in conjunction with this two simpler (i.e. less structured) models of
312 events are created, from which episodes are then formed as in Section 2.2 for comparison with the episodes
313 directly extracted from UKCP18r.

314

- 315 1. Model R_{day} : For each event, year and day are randomised, a uniform distribution. This is $E[n_a]$,
316 reflecting an Oct-Mar climatology approach (e.g., Champion et al., 2015; Smith and Phillips, 2012;
317 Stephan et al., 2018), or a business-as-usual case in (re)insurance (e.g., Hadzilicos et al., 2021; Hillier et
318 al., 2024).
- 319 2. Model R_{year} : For each event, only year is randomised. All relationships to proximal events within a time-
320 series are broken up to and including inter-seasonal timescales, yet seasonality (i.e. the pattern of
321 frequency as time progresses through a winter) is retained. This avoids pre-supposing a Dec-Feb peak
322 storm season (e.g., Manning et al., 2024; Martius et al., 2016), as this may change in future.

323

324 Episodes created from events directly extracted from UKCP18r contain real-world dependencies (e.g., storms
325 triggering both wind damage and flooding), whilst dependencies do not exist in models R_{day} and R_{year} . Thus, the

326 difference between co-occurrence in modelled worlds with and without dependency (i.e. U , Eq. 4) reveals the
327 effect on co-occurrence of those dependencies; i.e. models R_{day} and R_{year} are directly equivalent to a null
328 hypothesis, what could happen only by chance, the basis of all inferential statistics. The relative sizes of uplift
329 U for different window lengths (e.g. $\Delta t = 3, 21$ days) allows insight into phenomena that act on different
330 timescales (e.g. storms, or clusters of storms). A key advantage of this simulation approach is its simplicity.
331 Designing a statistical model to replicate observations requires the multiple choices in the selection of
332 statistical distributions and parameters, but there are no such choices here.

333

334 Note that all randomisation is conducted separately within each ensemble member. This is cautious (i.e.
335 perhaps less significant p -values) but remains valid even if the 12 ensemble members of UKCP18r are not a
336 truly random sample. Randomisation is repeated 5 times, giving 1140 simulated years in total, 228 for each
337 statistical model run. The chance (p -value) of occurrences in UKCP18r occurring in the simplified models can
338 then be assessed by taking each as a null hypothesis H_0 (i.e. Fig. 5, Fig. 6). Here, for episodes, uplift U_ϵ is the
339 total count of the number of events (n_a) over threshold within episodes.

340

341 *2.4. Jet Stream metrics*

342

343 One widely used and relatively simple metric of jet position is that of Woolings et al. (2010). This diagnostic
344 uses four low-level wind fields (925-700 hPa) to quantify the latitude and speed of the eddy-driven jet stream.
345 It is zonally averaged over the North Atlantic (0-60°W, 15-75°N), low pass filtered with a 10-day window to
346 remove effects from individual synoptic systems, then the maximum westerly wind speed across the latitudes
347 is taken to locate and quantify the jet. Data used here (McSweeney and Bett, 2020) are taken from the UKCP18
348 global model, which drives the regional model used in this paper.

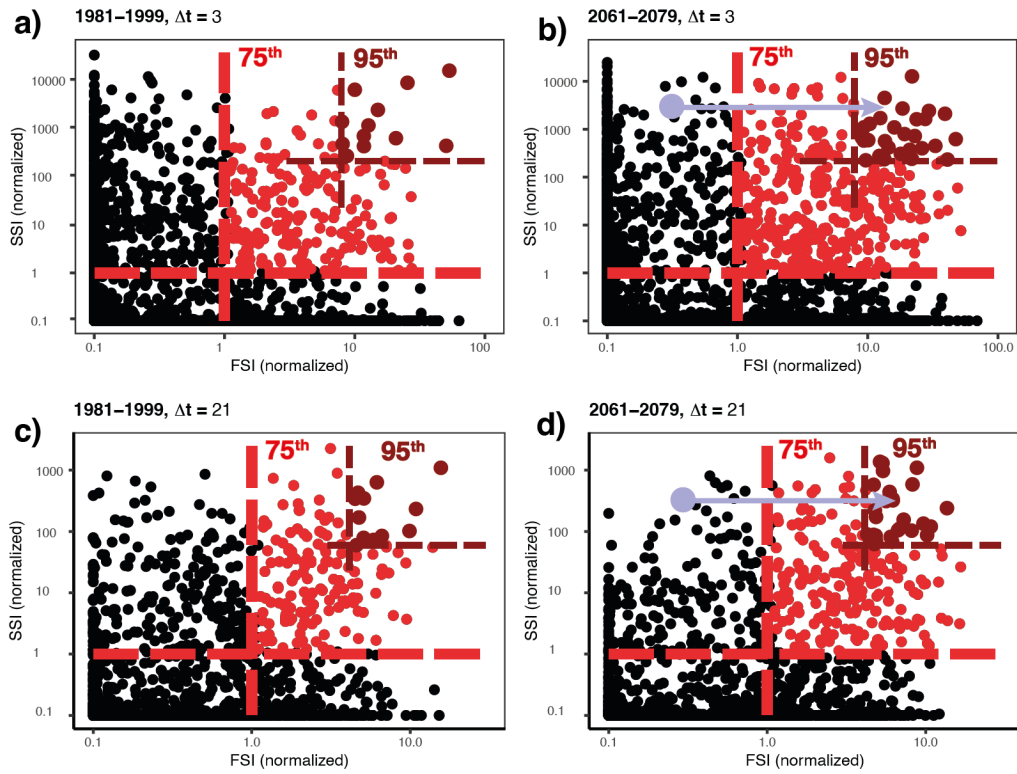

349

350 **3. Results**

351

352 Visually, on Fig. 4, a first impression is that the number of more severe joint episodes (ϵ_j) increases in a future
353 climate. This is investigated further for a range of time periods and thresholds (Section 3.1). Then, distribution
354 by month or 'seasonality' is explored (Section 3.2). Finally, the jet stream is examined as a possible cause of the
355 observed patterns (Section 3.3).

Fig. 4 Scatter plots of the summed severity of potential flooding (FSI) and extreme wind (SSI) for 3-day episodes for a) present and b) future time slices relative to the 75th percentile of these measures. Two thresholds are shown, the 75th percentile (red) and 95th percentile (dark red). Thresholds for 1981-1999 are used in all panels. c) and d) are the same, but for 21-day episodes. Light blue arrows visually highlight the tendency for FSI to increase into the future, which is particularly prominent for $\Delta t = 21$.

3.1. Uplift factors

Uplift (U_ε) is the number of times is more common co-occurrences are in UKCP18r than expected for independent events uniformly distributed across Oct-Mar (i.e. R_{day} , pink). Fig. 5a clearly shows two patterns (red lines) for the present.

1. U_ε is broadly two to four for all Δt (1-180 days) and percentiles (75th to 99th), but difficult to detect for seasonal timescales.
2. U_ε is highest for more extreme events (i.e. rarer, larger percentiles) and at shorter time windows (i.e. smaller Δt).

Visually, U_ε is similar in future (Fig. 5b), best seen by comparison to the grey vertical lines which are identical in each panel. As U_ε is relative to a baseline ($R_{\text{day}}, E[n_a]$) that accounts for the total of severe events (i.e. $n_a + n_b + n_c$, see Fig. 3b) increasing in future, it isolates the potential change in the dependence structure (i.e. level of 'correlation'). Illustratively, for $\Delta t = 3$ at the 95th percentile in 2061-2079 (ε_j^{95}), the UKCP extract that includes dependence has a 23-year return period (red line, Fig. 5d), which is considerably lower than the 104-year value

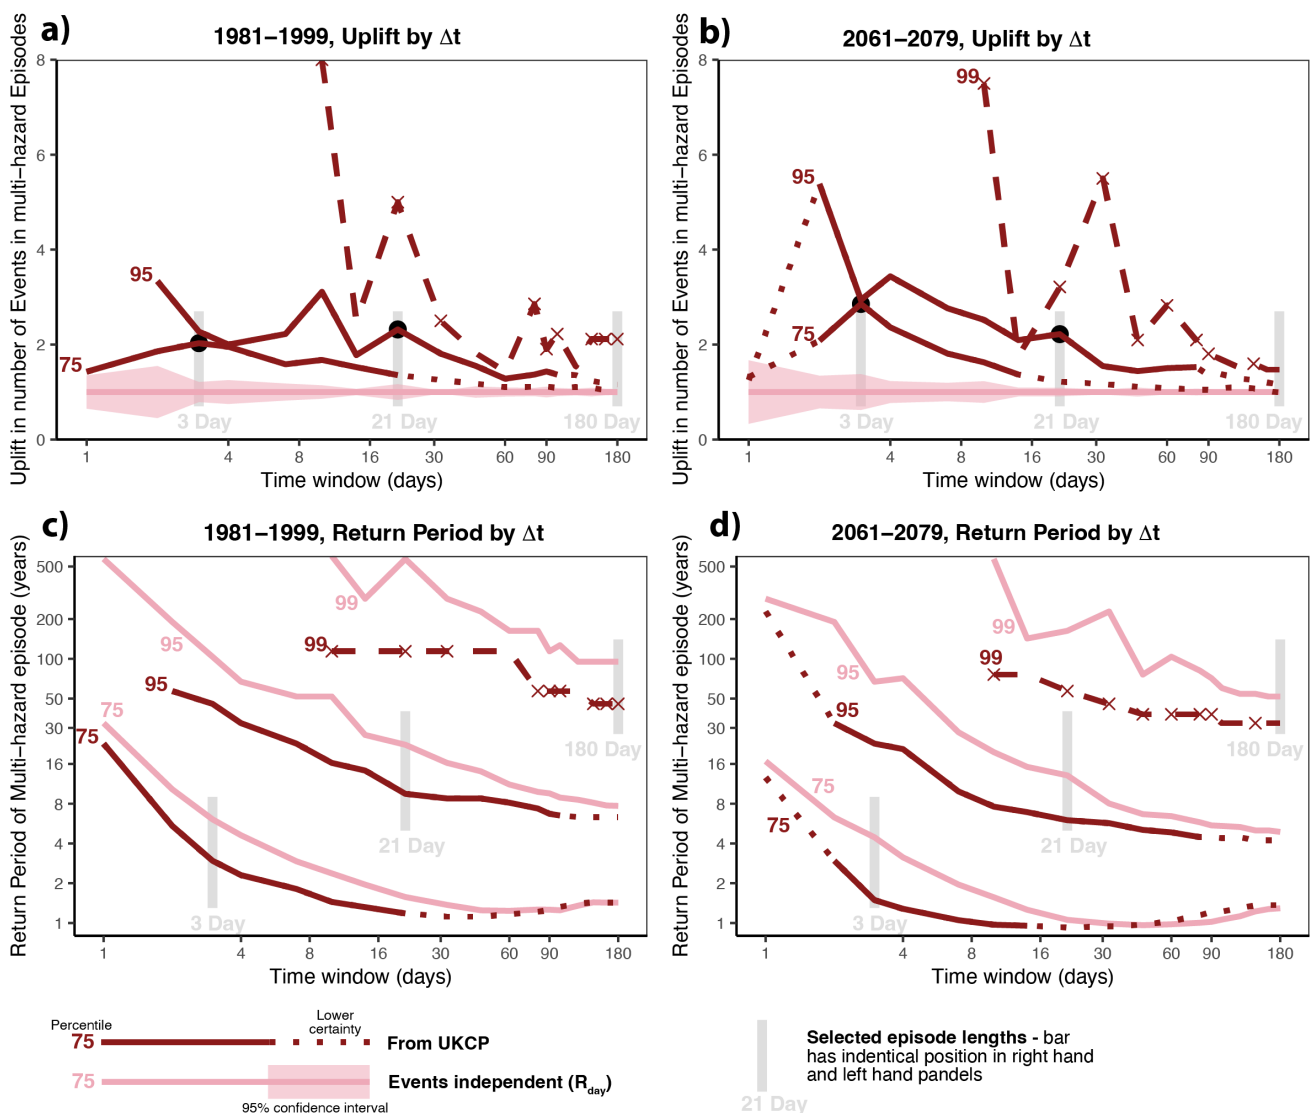

379 for the simulation that enforces an assumption of independence (pink line). Return periods (RPs) in Fig. 5c,d
 380 are simply calculated based on the number of *episodes* (n_{ϵ}) that exceed a severity threshold for a given Δt (i.e.
 381 $RP = \text{years}/n_{\epsilon}$). As such, the increased number of high-flow events is reflected in RPs reduced to about half
 382 their present value.

383

384 For 1-day windows, the act of collapsing events to a single day (t_{max}) will tend to underestimate co-
 385 occurrence, as flooding is expected to peak the day after wind given that water takes time (typically up to 24h)
 386 to flow into and through GB's rivers (De Luca et al., 2017); daily or storm-based analyses (Bloomfield et al.,
 387 2023; Manning et al., 2024) will be less influenced in this particular.

388

389

390

391 Fig. 5: Enhancement in co-occurrence, for a range of window lengths (Δt) used to create episodes. a) Uplift in number of events involved
 392 in multi-hazard episodes (1981-1999) as compared to a baseline of independence (pink line, R_{day}). Solid red lines are statistically
 393 significant, unlikely from variability within the independent case (pink shading is 2σ) assessed by simulation. Joint episodes ϵ_j^{75} are
 394 labelled '75', and so on. The Black dots situate the analyses of Fig. 6 within this plot. Dashed line indicates lower subjective confidence

395 as occurrences get low, with x marking statistically significant points. Dotted lines on Fig. 5 indicate that caution is needed, where
396 episodes occupy >10% of time because 'remnant' time periods left between already created episodes might start to appear, or where the
397 observation is not clearly different from the baseline (i.e. $p > 0.05$) because n becomes low or the difference small. c) & d) Return period
398 of multi-hazard episodes at 3 percentiles (75, 95, 99). Note that the grey bars are identically positioned on a) and b), and on c) and d).

399

400 3.2. Seasonality

401

402 Distribution by month of the co-occurrence of severe episodes, their seasonality, is explored in Fig. 6 at the key
403 timescales of $\Delta t = 3$ and 21 days using ε_j^{75} and ε_j^{95} , respectively. Since a longer window is more likely to contain
404 extreme events, a higher threshold captures sufficient events for $\Delta t = 21$. There are three pertinent features:

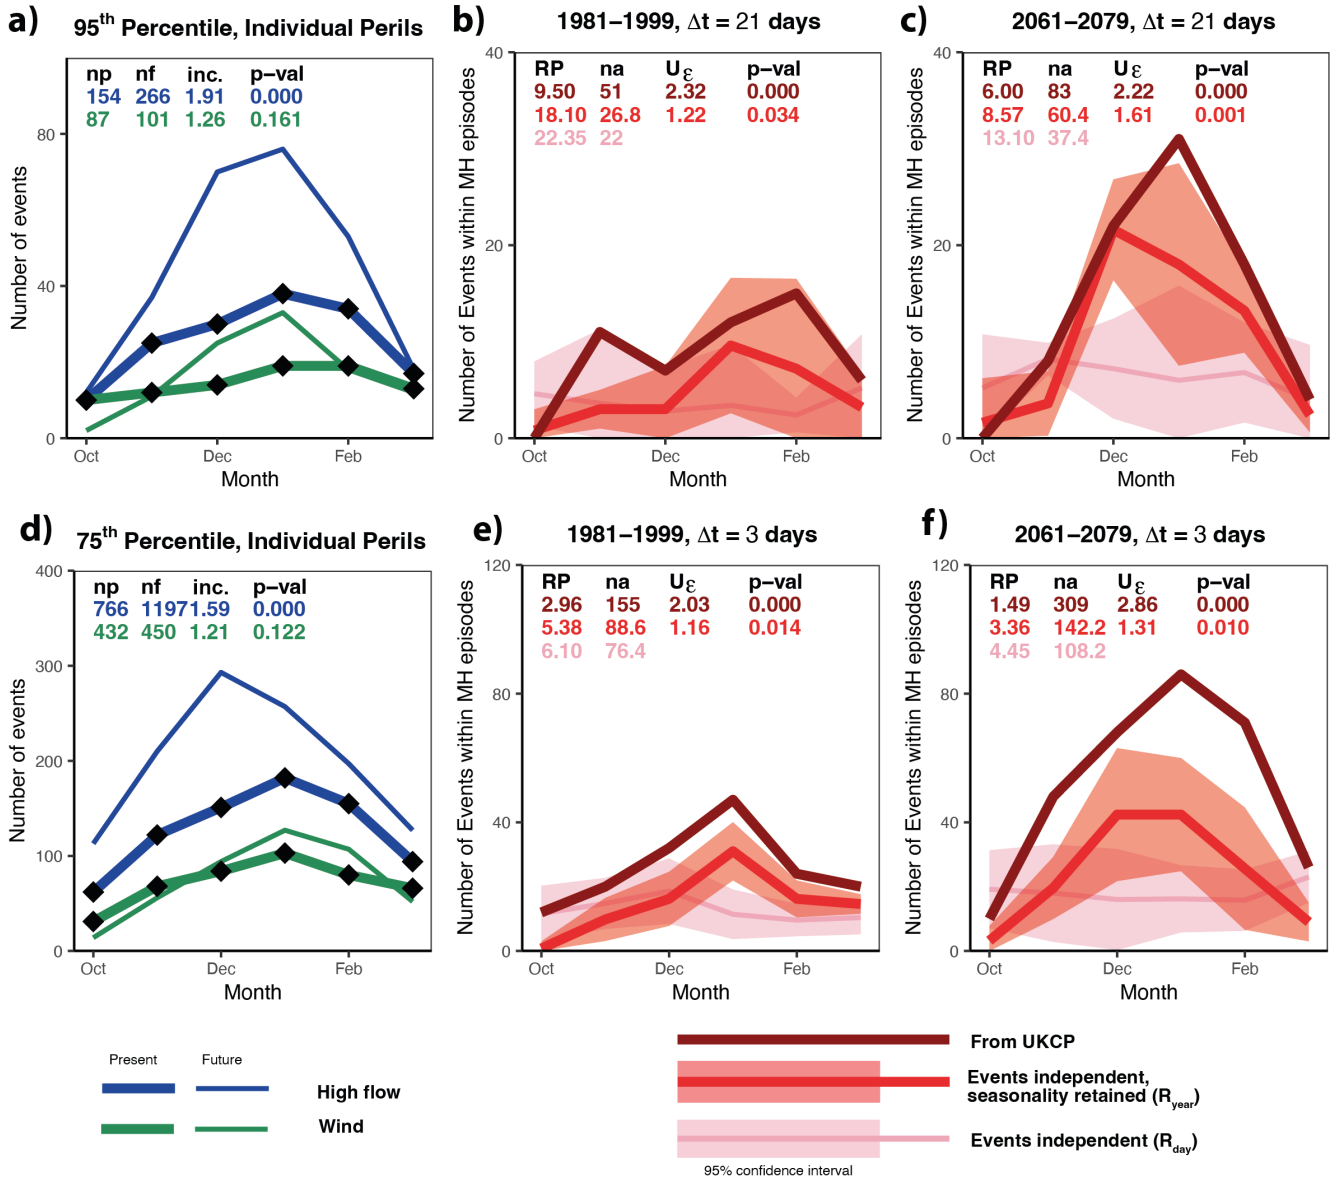

405

- 406 1. Considered individually (Fig. 6 a,d), both high flows and wind are notably more seasonal in future,
407 more concentrated in midwinter (December to February); the exception is lower (75th) percentile
408 flows. This effect is greater for the higher (95th) percentile.
- 409 2. U_ε is 2-3, present and future, aligning with Fig. 5.
- 410 3. For $\Delta t = 21$, the red line (R_{year}) is only a little below the UKCP18r occurrences (dark red), so at a storm-
411 sequence timescale of weeks ($\Delta t = 21$) U can largely be modelled by seasonality (i.e. R_{year}); the small
412 but significant difference in January and February in future is worth noting for investigation in further
413 research. However, on a shorter timescale ($\Delta t = 3$), an additional physical mechanism must be invoked
414 that operates on a shorter time-scale, that of a single storm or storms in fairly rapid sequence (i.e. $\Delta t \sim$
415 2-10 days).

416

417 Note that the seasonality effect in this bootstrap modelling (R_{year} , Fig. 6c) arises simply due to more events
418 being placed (e.g. by a broader-scale atmospheric driver) in a restricted timeframe. Illustratively, consider a
419 daily analysis of 10 winters each comprising 100 days, containing 50 floods and 50 wind extremes in total. If
420 uniformly distributed (i.e. Poisson randomness), the expected number of co-occurrences is $0.05 * 0.05 * 1000 =$
421 2.5 coincidences (e.g., Bevacqua et al., 2021; Hillier et al., 2015). Now, compress these into the central 50 days,
422 the expectation is $0.1 * 0.1 * 500 = 5.0$ coincidences.

Fig. 6: Seasonality of individual events (E) and multi-hazard episodes (ϵ). a) Seasonality of events for all high-flows (blue) and extreme wind (green) exceeding the 95th percentile. Thick lines represent 1981-1999 and thin lines 2061-2079. n_p & n_f are total counts for the present and future, respectively. 'inc.' is the mean increase (multiplier) from present to future for the 12 ensemble members with the p -value for the total count assessed using their variability (t-test). b) and c) Number of events in multi-hazard episodes ϵ_j^{95} from UKCP18r (dark red), simulations with dependency broken but retaining seasonality (red, R_{year} model), and independent phenomena (pink, R_{day} model). Coloured ribbons are 2σ , assessed by simulation. RP is return period of episodes in years, and p -values are calculated using variability of statistical model runs R_{day} and R_{year} (t-test). c) as for b) except for the future climate period. d-f) as for a-c), but for the 75th percentile and $\Delta t = 3$.

3.3. Jet Stream

Fig. 7 investigates the jet stream as a potential physical mechanism for the uplift U that cannot be explained by seasonality for 3-day episodes (ϵ_j^{75}) identified in Section 3.2. Jet characteristics for the days of these episodes are plotted, with other subsets (ϵ_F^{95} , ϵ_W^{95}) (see Fig. 3a) and average values for time blocks (e.g. Dec-Feb)

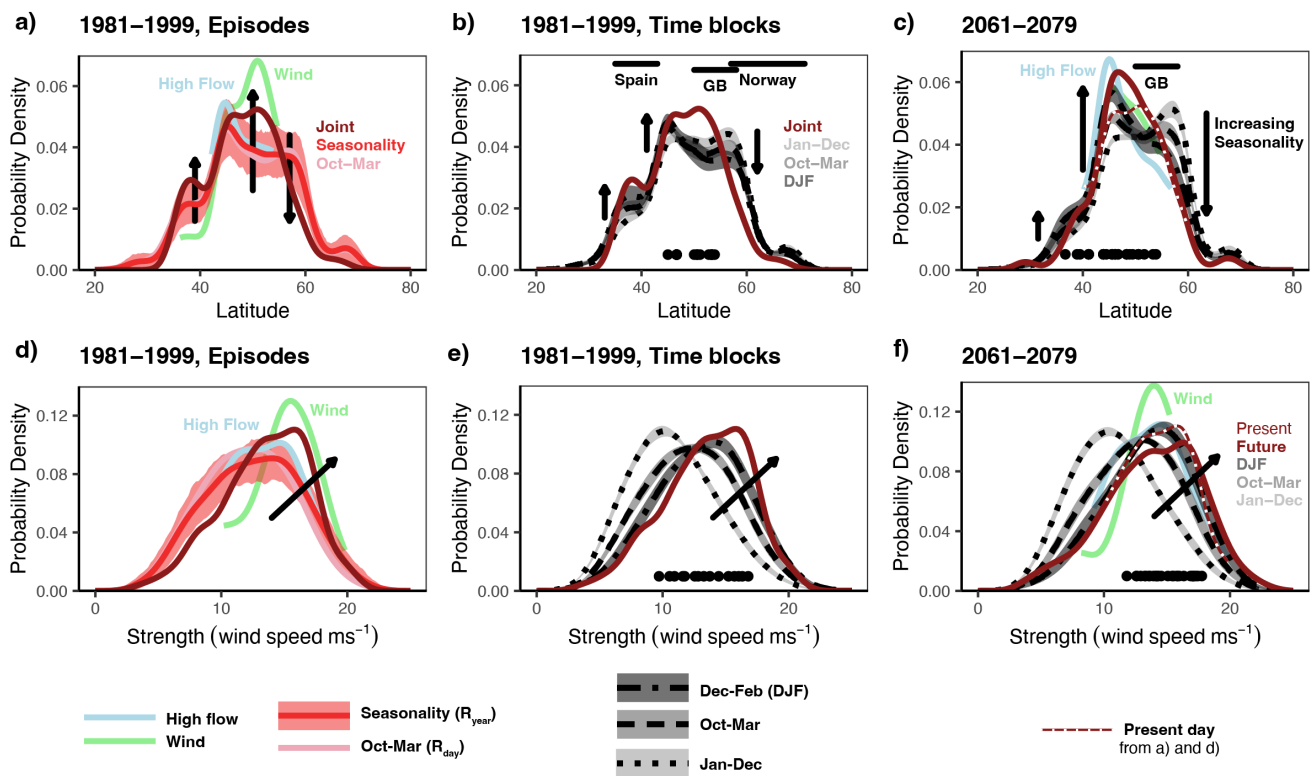

439 displayed for comparison. Fig. 8 presents a differently derived view, maps of westerly wind velocity anomalies
 440 on t_{max} days. Exact consistency between the two is not expected.

441

442 A number of features support the reliability and relevance of the main results to follow. First, in Fig. 7 subsets
 443 (e.g. ε_J^{75} , ε_W^{95}) are distinct from time blocks and the statistical models (R_{year} , R_{day}). This simply would not happen
 444 if there were a mis-match (e.g. in timing) between the metrics of the jet in the global model (McSweeney and
 445 Bett, 2020) and extreme weather extracted here for GB from the regional model. Second, the present day
 446 trimodal peak in ERA-40/ERA-Interim, matched ‘reasonably well’ by UKCP18r (McSweeney and Bett, 2020;
 447 Woollings et al., 2010), is present (Fig. 7a,b). Third, on days that severe weather occurs in GB jet-related wind
 448 anomalies occur over NW Europe, not elsewhere, (Fig. 8) indicating that the jet metrics (McSweeney and Bett,
 449 2020; Woollings et al., 2010) are relevant to the study area.

450

451

452

453

454 Fig. 7: Jet latitude (top row) and strength (bottom row) in UKCP18r (McSweeney and Bett, 2020) associated with $\Delta t = 3$ joint high
 455 flow and extreme wind episodes (ε_J^{75}), present and future. Curves are density estimates (Gaussian kernel, $\sigma = 1.0$ for strength and σ
 456 $= 2.0$ for latitude), and arrows illustrate trends identified in the data. In panels a) and d), the light red line is sampling preserving
 457 the distribution of storms’ dates within a season (i.e. R_{year}) and the pink lines are for Oct-Mar (i.e. R_{day}), and the error ribbon is 10th-
 458 90th quantiles for these storms as estimated from 100 random realisations. Uncertainty for the selected seasons (b,c,e,f) is shown as
 459 grey shading and is $\pm 2\sigma$ stderr of the 12 ensembles of UKCP18r. For visual clarity, only the parts of the wind and high-flow curves
 460 (ε_W^{95} , ε_F^{95}) are shown where they differ notably from the other curves. Dots are the most extreme events (ε_J^{95}). Bars in b) and d)
 461 show the latitude ranges of illustrative countries. All days within each episode are used.

462 For 1981-1999 joint severe episodes' (ε_J^{75} , dark red line) jet strength and latitude differ discernibly from
463 conditions at the times of year that they typically occur (i.e. R_{day} , red line and shading in Fig. 7) and from
464 average Oct-Mar conditions (R_{day}); Oct-Mar curves match those for non-severe storms ($\varepsilon_J^{<75}$) very closely,
465 although these are not shown for visual clarity (Fig. 7). Extremes also differ from a jet typical of the mid-winter
466 DJF storm season. Specifically, the four differences are:

467

- 468 1. Days with only high flows (ε_F^{95}) have jet latitude frequency peaks at 45°N, marginally elevated above
469 the seasonal expectation (Fig. 7a). Similar is true for jet strengths (Fig. 7d, Fig. 8b).
- 470 2. Potentially damaging winds in isolation (ε_W^{95}) are associated with a strong jet typically focussed on 45-
471 55° latitude range (Fig. 7a,d) with a jet speed anomaly at relatively high latitudes (50-60°N) extending
472 across the Atlantic (Fig. 8a).
- 473 3. Jet latitude for joint ε_J^{75} episodes peaks distinctly at 50°N (Fig. 7a,d, Fig. 8c). Self-evidently this is largely
474 due to GB's latitude (Fig. 7b) because storms used here must impact GB, and the southwards
475 displacement in this subset is highlighted with vertical arrows (Fig. 7a).
- 476 4. The peak in ε_J^{75} jet latitude is between the ε_F^{95} and ε_W^{95} peaks (Fig. 7a), and their jet strength is
477 intermediate in a progression from the high-flow to wind curves (Fig. 7d, arrow). In map view, the joint
478 ε_J^{75} anomaly is also a blend of those from the individual hazards (Fig. 8a-c). A southerly lobe extending
479 into the mid-Atlantic (20-40°W) is also notable.

480

481 Overall, co-occurring events in 1981-1999 appear to be associated with a jet that blends characteristics of the
482 most severe high-flow inducing events (i.e. similar to expectations for the time of year) with the severest wind
483 events. This is true even for the most severe episodes (i.e. ε_J^{95} shown as black dots, $n = 5$ with a RP of 44.8
484 years).

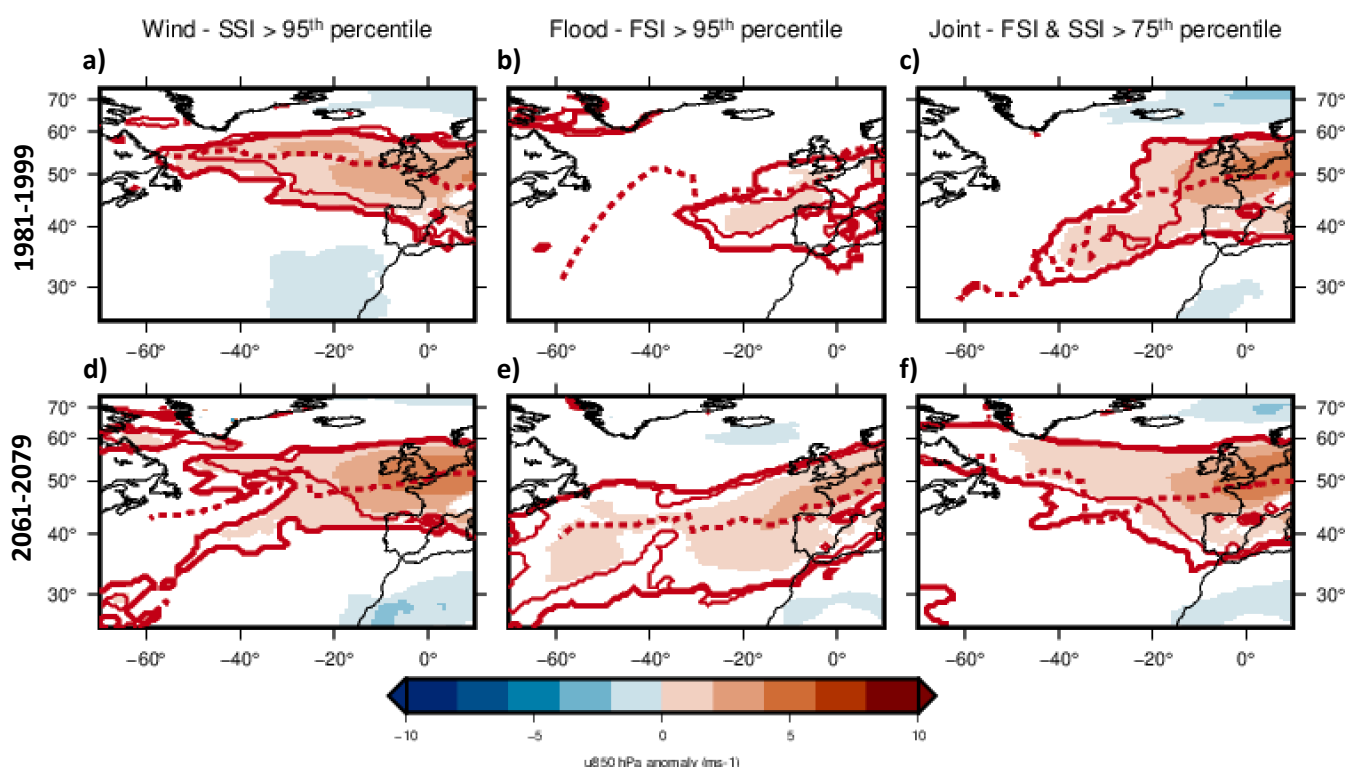

485

486 How does the jet strengths and latitudes change for 2061-2079? Broadly, most patterns are similar in their
487 character to 1981-1999, but with some important changes in relative magnitudes. The main changes are:

488

- 489 1. In future, jet strength and latitude anomalies (ε_J^{75} , ε_W^{95} , ε_F^{95}) are of higher amplitude with respect to
490 1981-1999 (Fig. 7, Fig. 8), insensitive to the exact baseline chosen (e.g. R_{year} , non-severe).
- 491 2. For jet latitude, the peak for joint extremes (ε_J^{75}) shifts $\sim 3^\circ$ southwards, as do the conditions for the
492 individual hazards, perhaps caused by the enhanced future seasonality of the jet which shifts
493 southwards in midwinter despite an overall (Jan-Dec) shift northwards (Fig. 7c).
- 494 3. Future DJF jet strength is similar to the present-day jet states for joint storms (Fig. 7f).
- 495 4. In map view (Fig. 8) anomalies for future wind episodes remain in a similar location, those for high
496 flows expand south and west, and the anomaly for joint hazards like in 1981-1999 shares

497 characteristics with both; in Europe it extends to Iberia like for high-flows, but across the Atlantic at 50-
 498 60°N like wind. This is a switch from a high-flow like pattern to a wind-like one (see Section 4.4).
 499
 500 In short, mean future DJF jet conditions tend to adopt a latitude that characterises high-flows in GB today and a
 501 jet strength typical of joint extremes today (Fig. 7c,f). Thus, in future, typical shorter-term ($\Delta t \lesssim 10$ days)
 502 midwinter jet states appear like those characteristic of impactful compound storms today, aligning with the
 503 observation that ε_j^{75} become more focussed in DJF (Fig. 6). The most severe episodes (ε_j^{95}) reflect this, being
 504 twice as frequent with a somewhat stronger and more southerly jet (i.e. $n = 10$, RP 22.4 years, Fig. 7).
 505

506
 507 *Fig. 8: Plan view of eddy-driven jet anomalies during stormy episodes ($\Delta t = 3$) in comparison to the Oct-Mar climatology. Composites of*
 508 *daily mean zonal wind velocity at 850 hPa for (a) dates of wind extremes (ε_W^{95} , $n=74$), (b) high-flow extremes (ε_F^{95} , $n=135$), and (c)*
 509 *days where both are extreme (ε_j^{75} , $n=77$). (a)-(c) are for 1981-1999, and (d)-(f) are for a future climate. Days used are only the most severe*
 510 *day within an episode (i.e. t_{max}). Solid red lines outline areas where the positive anomaly is significant ($p < 0.05$) for one-tailed t-test for*
 511 *difference between means of 12 ensemble members (climatology) and severe episodes. For comparison, thin red outlines are for a DJF*
 512 *climatology, and dashed line is the most significant point at each longitude for a higher-level jet (u_{250}). Hobo-Dyer (i.e. 37.5° standard*
 513 *parallel) cylindrical equal area projection, with -30° meridian. Note that f) is reconciled with Fig. 7c by realising that those data (u*
 514 *maximum) typically occur near NW Europe.*

515
 516

517 4. Discussion

518

519 Co-occurring flooding and extreme wind in GB are part of a complex multi-hazard risk to society (e.g., Simpson
520 et al., 2021), and this paper considers these hazards using impact-based proxies (Hillier and Dixon, 2020), the
521 UKCP18r dataset and modelled river flows (Griffin et al., 2022b). Its aim is to understand the joint hazard and
522 its drivers. Other complexities, such as interactions between vulnerabilities or exposed infrastructure systems,
523 are not considered. This paper offers:

524

- 525 1. A first examination of the jet stream for events based on high-flow conditions, not extreme rainfall, in a
526 sentinel location for NW Europe
- 527 2. A multi-temporal ($\Delta t = 1-180$ days) approach that groups events into multi-hazard *episodes* in a way
528 that is relevant to stakeholders.
- 529 3. A new set of 3,427 wind events.
- 530 4. An examination of the role of seasonality in how high flows and extreme wind co-occur.
- 531 5. An assessment of relatively simple jet stream metrics (Woollings et al., 2010) in this context.

532

533 The work fits into a growing consensus on various aspects of potential episodes of joint wintertime flooding
534 and extreme wind in GB. These episodes are typically driven by extra-tropical cyclones (e.g., Hillier et al., 2015;
535 Manning et al., 2024; Owen et al., 2021a; PERILS: Losses, 2024), and associated with cyclonic or north-westerly
536 weather patterns in an NAO+ regime (Bloomfield et al., 2024; Hillier et al., 2020). Fig. 5 reinforces an doubling
537 in frequency in future climate projections, and also a x2-4 uplift (U) in co-occurrence over a baseline of
538 independence, a dependency that is not discernibly greater in future (Bloomfield et al., 2023; Manning et al.,
539 2024). The jet stream associated with high river flows is to the south of GB, whilst for wind extremes it is to the
540 north (Fig. 7a), consistent with ETCs being rainy on their northern flank and windy to the south (Manning et al.,
541 2024). And, Fig. 7c shows that potential flooding tends to shift southwards in future (Bloomfield et al., 2024). It
542 is also entirely in line with evidence that GB in future will be wetter (e.g., Lane and Kay, 2021; Lowe et al., 2019)
543 with more frequent and severe high-flows (Collet et al., 2018; Griffin et al., 2022b). Despite being heavily
544 validated, a caveat is that these studies rely on UKCP18r using the RCP8.5 emissions scenario, highlighting the
545 need for a multi-model study or other emission scenarios. An important aspect of the agreement across varied
546 approaches is that it demonstrates, through the episode definition used here, that previous work is applicable
547 to (re)insurance and other stakeholders and their experience of episodes.

548

549 On this theme, what is an appropriate baseline? Namely, what statistical model (e.g. days of non-severe
550 storms, uniform occurrence in DJF) should be chosen to represent independence between hazards for a
551 particular enquiry? An insurer's standard practice might involve independence across an Oct-Mar season today.
552 Then, illustratively (at $\Delta t = 21$) ε_F^{95} has a 1-year RP and ε_W^{95} has a 1-year RP, combining to be a 22-year RP joint
553 episode assuming the R_{day} model, which is reduced 4-fold to a 6 year RP in 2061-2079 accounting for

554 dependence (Fig. 6b,c). If an insurer's modelling correctly includes the individual hazards seasonality, the
555 correction needed would be notably less (Fig. 6). Thus, a fixed timeframe for analysis such as DJF or Oct-Mar
556 (e.g., Zscheischler et al., 2021) should be used with caution, especially since peak months of (co-)occurrence
557 may shift in future, and practitioners and researchers must ensure the statistical approach aligns with the
558 research question posed.

559

560 Selected aspects of the results are now discussed.

561

562 *4.1. Co-occurrence for the most extreme events*

563

564 The initial estimate of uplift in co-occurrence between extreme winds and high-flow in rivers was ~ 1.5 times
565 (Hillier et al., 2015). A value of $\sim 2-4$ times in UKCP18r for daily data (Bloomfield et al., 2023) is now confirmed
566 visually (Fig. 4) and statistically (Fig. 5, Fig. 6) for episodes like to cause loss (Appendix A.4), and appears robust
567 in that it is not overly dependent on the method, metrics, or time period (1981-1999, or 2061-2079) used in
568 the studies. Less well constrained is whether, in the limit, are these perils are asymptotically dependent or
569 independent? Namely, do the most severe events have a weaker or stronger tendency to co-occur? This is a
570 key question in assessing risk.

571

572 For ERA5 wind gusts and precipitation or GLOFAS derived river flow (at daily, weekly, monthly resolution),
573 residual tail dependence ($\bar{\chi}$) (Coles et al., 1999) does not tend to 1.0 as required for asymptotic dependence,
574 but equally gives no indication that correlation disappears into the tail of the distribution, with the same true
575 for monthly Network Rail delay data (Bloomfield et al., 2023; Vignotto et al., 2021). Indeed, in UKCP18r uplift U
576 increases from 2.4 to 3.4 as Bloomfield's threshold increases, an effect previously demonstrated by sensitivity
577 testing (Hillier and Dixon, 2020). Fig. 5 extends this, with systematic increases in U from the 75th to 99th
578 percentile (ε_j^{75} to ε_j^{99}) indicating that more extreme episodes co-occur more strongly (Fig. 5a,b), at least to
579 return periods of up to $\sim 50-100$ years (Fig. 5c,d).

580

581 Other metrics give a different view. Even as $\bar{\chi}$ or U increase or hold steady with increasing threshold, χ and
582 Spearman's r decrease (Bloomfield et al., 2023; Hillier and Dixon, 2020). Taking this further, for rain and wind,
583 with a Clayton copula best fitting their severity metrics for (UKCP18, 2.2 km) Manning et al (2024) implicitly
584 assume asymptotic independence for the most extreme events. Indeed, by taking parts of two winter seasons
585 and summer (i.e. Jan-Dec) it is possible to find negative correlations at higher thresholds and annual
586 timeframes (Jones et al., 2024). The variety highlights the importance of using measures attuned to each
587 study's purpose. U is a statistic that directly comments on the chance of two extreme events in a season, as in
588 some stress tests for insurers (Bank of England, 2022). It could also be used to force dependency between

589 independently derived (i.e., uncorrelated) event sets at selected percentile(s) (e.g. 75th, 95th, 99th) perhaps with
590 copulas (e.g., Hillier et al., 2023) to better estimate actual likely losses, improving on using one Spearman's r
591 value to represent dependency for all events causing notable losses (Hillier et al., 2024). Given these apparent
592 discrepancies, it would be beneficial to further investigate extreme winds and high river flows or flooding,
593 perhaps with larger model ensembles.

594

595 4.2. Co-occurrence across timeframes

596

597 How does strength of co-occurrence vary with the time-window (Δt) used to group events? Previous wind-flow
598 work using Spearman's r on regular, non-overlapping periods found it to increase for windows of up to 20-40
599 days and then hold steady, perhaps decreasing slightly for a whole season (Bloomfield et al., 2023). Fig. 5,
600 however, uses a measure of tail dependency to focus on the severe events (ε_j^{75}) thought to best represent
601 impactful events (Bloomfield et al. (2023), Appendix A.4), and indicates that uplift (U) is highest for shorter
602 time windows. Assuming UKCP18 correctly captures persistence, this overturns the working hypothesis in the
603 initial papers (Hillier et al., 2015; Hillier and Dixon, 2020). These looked at seasonal timescales, as the prevailing
604 yet unpublished view in 2015 was that individual storms were either wet or windy, and took evidence of wet
605 and stormy winters (Kendon and McCarthy, 2015; Matthews et al., 2014) to indicate that co-occurrence might
606 most strongly exhibit on long timescales ($\Delta t = 180$). Descriptively and numerically, understanding this trend in
607 strength of dependence with timeframe is useful for stakeholders who might have varied elements of their
608 business to risk assess, from operational (e.g. 3 day or 21 day long event durations in insurance contracts, or
609 railway repairs) to planning (e.g. annual regulatory or budgetary).

610

611 Understanding the relative dominance and interplay of the various hydrometeorological processes is less
612 readily achieved. The conceptual, multi-temporal model set out by Bloomfield et al (2023) details evidence for
613 shorter-term ($\Delta t \approx 1-15$ days) contributions from storms (i.e. sub-storm to storm clusters) and longer term
614 'memory', perhaps in GB groundwater or distant conditions (De Luca et al., 2017; Hillier et al., 2015) mediated
615 by atmospheric behaviours captured by weather patterns or the NAO index (Bloomfield et al., 2024; e.g., Hillier
616 et al., 2020). Whilst winters in GB and NW Europe can be undoubtably wet and stormy (Met Office, 2024), the
617 pattern in Fig. 5 adds weight to a case that processes at shorter timescales of a few weeks or less might
618 dominate (i.e. storms, or storm sequences) rather than a set of conditions established for a season (e.g. Arctic
619 sea-ice) dominating. But, any definite statement still seems premature. To aid progression to a process-
620 orientated view, future statistical simulation modelling to split out contributions at the various time-scales
621 (e.g., Hillier and Dixon, 2020) with a consistent metric (e.g. χ , U , r) is needed for high-flows and extreme wind.
622 Meanwhile, a more in-depth look at the jet stream states associated with extreme winds and high flows can
623 also contribute.

624

625 4.3. Utility of simple jet stream metrics

626

627 Extra-tropical cyclone (ETC) development is closely intertwined with the jet stream (Clark and Gray, 2018;
628 Dacre and Pinto, 2020; e.g., Geng and Sugi, 2001; Laurila et al., 2021). Illustratively, windstorms are located on
629 its poleward side and are more intense when the jet is stronger (Laurila et al., 2021), and ETC clustering is more
630 intense in GB with a strong persistent jet at $\sim 50^\circ\text{N}$ (Pinto et al., 2014; Priestley et al., 2017). So, it was logical for
631 Hillier and Dixon (2020) to propose the jet stream had a role in whether flooding and extreme wind co-occur or
632 not based on an ETCs relationship with the jet.

633

634 Practically, calculating an index to quantify the jet stream (Ayres and Screen, 2019; e.g., Woollings et al., 2010;
635 Zappa et al., 2018) is less demanding than cyclone tracking (e.g., Hoskins and Hodges, 2002; Manning et al.,
636 2024). So it is useful to ask if the relatively simply derived metrics for the eddy-driven (lower tropospheric)
637 North Atlantic jet of Woolings et al. (2010) can be a functional, readily applied tool to distinguish co-
638 occurrence. If so, by being computationally easier than running cyclone tracking algorithms, it should facilitate
639 inter-comparison of this potential driver of co-occurring high-flows and extreme wind between climate models
640 and reanalyses (e.g. CMIP6, ERA5, UKCP).

641

642 Fig. 7 (panels a,b,d and e) clearly shows that the jet stream index of Woolings et al. (2010) is able to distinguish
643 different large-scale jet dynamics associated with joint high-flow and wind events (ε_J^{75} , dark red line), providing
644 an easy answer to the question posed about utility. Specifically, wind (ε_W^{95}) and ε_J^{75} episodes have a stronger
645 jet than high-flows (ε_F^{95}), in accord with analysis of extreme precipitation and expectations that a weaker jet
646 causes ETCs to move more slowly allowing rainfall to persist for longer (Hillier and Dixon, 2020; Manning et al.,
647 2024). Indeed, Fig. 7 demonstrates how statistical significance testing using jet metrics can support this idea,
648 augmenting visual analysis (Manning, 2024). In future (2061-2079) latitude illustrates a case where signatures
649 of subsets are similar, with distinctions not clear-cut using only this index (Fig. 7c). So other views, such as on
650 the timing of episodes within a season or their planform distributions of associated high-level wind (Fig. 6, Fig.
651 8), are also useful to understand the influence of the jet stream.

652

653 4.4. Potential influences of the jet stream on future co-occurrence

654

655 Do dynamical (e.g. jet stream) or thermodynamic effects most control the co-occurrence? Previous analysis has
656 inferred that the future increase in co-occurrence is a predominantly thermodynamic response (i.e. warmer air
657 can be wetter, and therefore more high FSI events), assisted by southwards displaced cyclone tracks leading to
658 dynamically enhanced temperature (Manning et al., 2024). Fig. 6-8 allows this to be clarified.

659

660 First, consider 21 day episodes (Fig. 6a-c), likely associated with storm sequences (e.g., Bloomfield et al., 2023;
661 Dacre and Pinto, 2020; Mühr et al., 2022). For a start, simply doubling the number of high-flow events during
662 Oct-Mar in a wetter future world is insufficient (R_{day} , Fig. 6c). Interestingly, both high-flows and wind extremes
663 become more seasonal, focused into midwinter, particularly with higher percentiles (Fig. 6a,d, Appendix A,
664 Appendix B). An increased frequency of high flows across winter as a whole is an established idea (Griffin et al.,
665 2022b), but within this the increased seasonality has not been noticed as the only relevant study lacked data
666 over NW Europe (Ridder et al., 2020). Logically this phenomenon forces future co-occurrences to be more
667 focussed in Jan (Fig. 6c,f), and when this more intense seasonality is isolated and modelled (R_{year}) it is nearly
668 possible to explain the UKCP18r events (dark red line). So, at this timeframe, *if* atmospheric drivers distribute
669 extreme conditions correctly by month, thermodynamics are nearly sufficient to explain the increase in co-
670 occurrence in future. Fig. 7b,c demonstrates that mean UKCP18r jet stream latitude becomes more seasonal
671 in future, in wintertime shifting south (equatorwards) and focussing on 45°N to impact GB. A stronger and
672 squeezed future jet is in line with CMIP simulations (Oudar et al., 2020; Peings et al., 2018), so a latitudinally
673 squeezed wintertime jet might be the key dynamical driver of the increasingly seasonal future uptick in joint
674 events. A equatorwards shift is in line with the Polar Amplification Model Intercomparison Project (PAMIP)
675 findings where a sea-ice loss effect outweighs the polewards shift in the jet due to oceanic warming in this ‘tug-
676 of-war’ (Screen et al., 2022). A northwards historical (1979-2019) shift of the jet stream has been reported in
677 reanalysis products and climate model runs including UKCP18, inferred from a difference between mean zonal
678 wind velocity (500 hPa) at 40-50°N as compared to 20-30°N (Woollings et al., 2023). This, however, is readily
679 reconciled with our finding of a potential future southerly shift in the jet and that of ETC tracks (Manning,
680 2024), by considering Fig. 6b,c. In DJF, in the Atlantic at least, there is a *southwards* shift of the jet *into* the 40-
681 50°N bin, increasing typical wind speeds there with respect to that at 20-30°N. So, Fig. 6 provides an additional
682 insight into how broad-scale thermodynamic and dynamic factors combine to explain longer joint high-flow
683 and wind episodes.

684

685 For individual or closely consecutive storms ($\Delta t = 3$ days), Fig. 6e,f clearly shows that the number of events
686 alone is insufficient to cause the co-occurrences in UKCP18r, particularly in the future, even if enhanced
687 seasonality is accounted for (red line, R_{year}). So, another shorter-term explanatory atmospheric behaviour is
688 needed. Fig. 7 and Fig. 8 suggest that this is the disposition and dynamics of the jet stream. In terms of the
689 latitude and speed of the jet’s strongest part, the typical mid-winter jet becomes more like that characteristic
690 of impactful compound storms today (Fig. 7). Fig. 8 adds plan-view information on the jet at the time of high
691 joint FSI-SSI episodes impact GB. In the present, joint episodes (ε_j^{75}) have a jet that typically blends most of the
692 strength of wind events (ε_W^{95}) with the more southerly track of high-flow inducing events (ε_F^{95}). In future, a
693 stronger and more southerly jet is much more prominent for ε_j^{75} episodes (Fig. 7c, Fig. 8e), fitting with the

694 location of extreme precipitation (Bloomfield et al., 2024) and its associated jet (Manning et al., 2024) moving
695 south.

696

697 Future high FSI-SSI episodes (ε_j^{75}) better resemble wind episodes than high-flow (Fig. 8d-f), fitting with a view
698 of a typically rainy wintertime future GB where wind is typically the missing element for a joint event
699 (Bloomfield et al., 2024). Namely, wind becomes the limiting factor rather than flooding as it is now; currently
700 multi-basin high-flows needs multiple storms setting wet antecedent conditions (De Luca et al., 2017), and
701 locally the joint impact footprint's extent is limited by its rain component (Manning et al., 2024). Intriguingly, a
702 southerly jet anomaly during a compound storm's lifetime over the Atlantic (Fig. A1 - Manning et al., 2024) that
703 obtains a very windy signature when impacting GB (Fig. 8d,f) suggests the most severe future events might
704 arise from a jet initially passing over warm southerly water that strengthens and shifts north as it impacts
705 southern GB. So, in a modification to the conclusion of Manning et al. (2024) a relatively equal contribution of
706 dynamics (i.e. jet disposition and seasonality) and thermodynamical (i.e. warmer air carries more moisture) is
707 argued to drive future increases in joint hazard in GB.

708

709 Placing an emphasis on dynamics (e.g. jet stream) ties in with a broader, emerging picture of linked multi-
710 hazards across the Atlantic domain (e.g., Röthlisberger et al., 2016). Cold air outbreaks over eastern Canada
711 followed by wind extremes over northern Europe and the British Isles appear associated with an enhanced jet
712 stream (Leeding et al., 2023), whilst January being the dominant month for compound surge and rainfall
713 around GB (Bevacqua et al., 2020) ties to the same timing for wind and riverine high-flows (Fig. 6).
714 Furthermore, clustered ETC are associated with a jet stream anomaly focussed on GB (Dacre and Pinto, 2020;
715 Pinto et al., 2014; Priestley et al., 2017). And, like flow regimes globally, these relationships are likely to change
716 with the climate (e.g., Jiménez Cisnero and Oki, 2014; Li et al., 2024). We therefore advocate a process-
717 orientated approach to co-occurring hazards (e.g., Manning et al., 2024), highlight that the 'recipe' of driving
718 large-scale conditions (e.g. jet stream state) for such a 'perfect storm' (e.g., Hillier et al., 2023) will vary by
719 country (Gonçalves et al., 2023; Raveh-Rubin, 2015; Röthlisberger et al., 2016), and advocate the application of
720 our novel methods in other regions.

721

722 **5. Conclusions**

723

724 This study uses novel statistical modelling of dependencies and a jet stream index (Woollings et al., 2010) to
725 understand the co-occurrence of high-flows and extreme wind events in multi-hazard *episodes*, with a focus on
726 3-day and 21-day durations. The idea of dynamically defined episodes that group events to reflect periods of
727 adverse conditions is defined to reflect lived experience, and extracted using the FSI (Bloomfield et al., 2023,

728 2024) and SSI indices (e.g., Klawns and Ulbrich, 2003) from the UKCP18 regional 12km dataset which has
729 previously been validated (Bloomfield et al., 2023). The main conclusions are:

730

- 731 • Defining stormy multi-event episodes as they are experienced (i.e. dynamically positioned time
732 windows) produces results that align with previous work, giving stakeholders additional comfort in
733 using published results.
- 734 • This said, statistically, it is critical to note that different dependency measures (e.g. χ , U , r , τ) reflect
735 different aspects of distributions of joint extremes, and may even appear contradictory. Also, using
736 fixed timeframe for analysis (e.g. Oct-Mar, DJF) should be used with caution, especially since peak
737 months may shift in future. Statistically modelling seasonality in a month-by-month analysis as done
738 here may be necessary.
- 739 • Uplift (U) in co-occurrence is found to increase as severity increases (e.g. 90th to 99th percentile),
740 meaning that evidence is starting to suggest that dependence exists to high return periods, even if not
741 strictly 'asymptotic'. So, ignoring correlation underestimates risk most for the strongest storms.
- 742 • Uplift is found to increase as Δt is reduced, highest within insurers' key windows ($\Delta t = 3,21$ days),
743 suggesting the importance of atmospheric mechanisms that act to drive co-occurrence at timescales of
744 days to weeks (e.g. storm sequences); see the framework model in Bloomfield et al. (2023). So,
745 ignoring correlation underestimates risk most for individual or closely grouped storms.
- 746 • Jet stream metrics (e.g., Woollings et al., 2010) are found to be a useful, easily determined tool to
747 investigate its roles as a driver of co-occurrence.
- 748 • Future strong jet streams become increasingly focussed in mid-winter (Dec-Feb) driving the increased
749 seasonality in individual hazards, a larger effect for more extreme events. This broad-scale dynamic
750 effect, combined with thermodynamics (i.e. a warmer, wetter world), explains most of the uplift in
751 future joint events at storm-sequence timescales ($\Delta t = 21$ days) and over.
- 752 • For individual or closely consecutive storms ($\Delta t = 3$ days), altered jet characteristics are also needed to
753 fully explain the uplift in co-occurrence, stronger and displaced southwards as storms impact GB. In
754 short, typical future DJF jet variability closely resembles that of impactful compound storms in GB
755 today highlighting the contribution of the jet changes to the increase in extremes.

756

757 Future work will could unpick and quantify the balance between dynamic and thermodynamic effects, ideally
758 using higher resolution data from a variety of climate models. It will be important, however, to build area-by-
759 area understanding of how the impact of common drivers varies spatially to improve risk mitigation and
760 planning (e.g. diversification, mutual aid across Europe). As the jet stream guides storms to one region, another
761 will be spared.

762

763

764 **Conflict of interest statement**

765

766 No conflicts of interest.

767

768 **Acknowledgements**

769

770 To undertake this work Hillier was funded by a NERC, UK Knowledge Exchange Fellowship (Grant Number
771 NE/V018698/1). Bloomfield, Shaffrey, Bates and Kumar are part-supported by the UK Centre for Greening
772 Finance and Investment (NERC CGFI Grant Number NE/V017756/1), which Hillier is associated with as an
773 Associate Research Fellow. Thanks are given to Adam Griffin at CEH and the AquaCAT project, who developed
774 the UKCP18r based river flow simulations, advised about them and provided a daily time-series to accompany
775 them. Garry and the AquaCAT project were funded under the UK Research & Innovation Strategic Priorities
776 Fund UK Climate Resilience programme, co-delivered by Met Office and NERC on behalf of UKRI partners AHRC,
777 EPSRC and ESRC.

778

779 **Authors' contributions**

780

781 The work was conceived by JH with input from HB, PB, LS. Analysis was by JH, with input from HB. DK created
782 Fig. 1. FG was involved in data acquisition and project conceptualisation. Writing and interpretation was led by
783 JH with input from all authors.

784

785 **Data availability statement**

786

787 UKCP18 data are available from the Met Office. Flooding events are from Griffin *et al* (2022a) on the CEDA
788 repository. Wind and precipitation events are available on Zenodo (10.5281/zenodo.14282051) and have been
789 submitted to the CEDA archive (<https://archive.ceda.ac.uk/>).

1124 **Appendix A: Event Sets**

1125

1126 *A.1 Dataset selection & fields used*

1127

1128 This study uses the UK Climate Projections 2018 (UKCP18) regional simulations. On a 12 km grid, over the
1129 commonly used EURO-CORDEX domain (Jacob et al., 2014), simulations were run from 1980–2080 using the
1130 Representative Concentration Pathway (RCP) 8.5 climate change scenario with 12 member perturbed
1131 parameter ensemble (Tucker, et al., 2022). Hourly 10m instantaneous wind gusts and total precipitation were
1132 available from the 12 ensemble members for two periods (1981–2000, 2061–2080), and UKCP18r-based river
1133 flows for these two time periods have been derived (Griffin et al., 2022b) by using the simulated precipitation
1134 and temperature, and derived evapotranspiration, to drive the Grid-to-Grid (G2G) hydrological model (Kay et
1135 al., 2021). From these daily mean river flows output by G2G on a 1 km grid over GB, a set of high-flow events
1136 was created and is openly available (Griffin et al., 2022a). A daily time-series of the area subject to extreme
1137 high flows was also provided to the authors.

1138

1139 Thus, UKCP18 is selected as it presents the opportunity for more extreme wind and high-flow events to be
1140 analysed than in the observational record, and for future changes to be examined. The UKCP18r simulations
1141 are argued to well represent extreme precipitation (Cotterill et al., 2021; Lane and Kay, 2021; Lowe et al., 2019;
1142 Tucker, et al., 2022) and wind gusts (Manning et al., 2023) when assessed against lower resolution climate
1143 model simulations and gridded historical observations. Importantly, rank correlation between GB aggregated
1144 precipitation, high-flows and extreme wind for the simulated present (1981-2000) closely matches the ~30 km
1145 resolution ERA5 reanalysis (1979-2021)(Hersbach et al., 2020) and GLOFAS river-flows derived from it using
1146 LISFLOOD (Harrigan et al., 2023; Hirpa et al., 2018) across time windows from 1 to 180 days (Bloomfield et al.,
1147 2023). In other words, even after higher-resolution verification (i.e. against CAMELS-GB/CHESS-MET), the
1148 UKCP18r simulations appear to adequately capture co-occurrence of the extreme wind and high flows
1149 (Bloomfield et al., 2023, 2024).

1150

1151 *A.2 Defining widespread hazard-specific events*

1152

1153 For the present time period, 1981–1999, UKCP18r has 19 complete extended winters over 12 ensemble
1154 members, giving 228 simulated seasons designated here by the year they start in (i.e. Oct 1981 – Mar 1982 is
1155 ‘1981’). These contain unrealised yet plausible extremes. Griffin et al. (2022a, b) used the 99.5th percentile of
1156 flow across the *whole* year ($q_{i,j}^{99.5}$, Jan-Dec) and required that greater than 0.1% of the area of the GB river
1157 network (19,914 grid cells, ~20 km²) exceed its threshold to constitute being within an event (blue shaded
1158 areas in Fig. 2). In addition a 14-day maximum event length was imposed, and events sub-divided if flow

1159 dropped to under 1/3 of the lowest of two included peaks which were separated by at least an estimated time-
 1160 to-peak of storm hydrographs. This is a point-over-threshold approach (e.g., Lechner et al., 1993; Robson and
 1161 Reed, 1999) and their intention was to isolate hydrologically independent, extreme and widespread events.
 1162 Here, matching sets of events for extreme wind, and for completeness precipitation, are extracted.

1163
 1164 Grids of daily totals of precipitation (p) and maximum 10m wind gust (v) are created, and used to define events
 1165 (E). Each event is the spatial footprint of the maxima driving that hazard (e.g. v) over a time-window
 1166 containing an isolated hydro-meteorological extreme.

1167
 1168 For wind events, a daily time series for v of the areal fraction of GB where it exceeds its grid cell's 98th
 1169 percentile ($v_{i,j}^{98}$, Oct-Mar) is first computed (Fig. 2). Then, the temporal limits (t_{start} and t_{end}) of the extreme
 1170 event days are defined as the first and last day of a period where this areal fraction is at least 0.1% of the whole
 1171 GB land area (~300 km²). 0.1% is used for consistency with flooding (Griffin et al., 2022a), and the 98th
 1172 percentile aligns with a recent consensus for wind impact estimation (e.g., Bloomfield et al., 2024; Klawns and
 1173 Ulbrich, 2003; Priestley et al., 2018) outlined in Appendix A.3. Thus, based on these thresholds, each event
 1174 consists of a sequence of consecutive extreme days, with the maximum windspeed (v) across the duration of
 1175 the event retained at each location to give an event its footprint. No wind event ever exceeds 8 days ($95\% \leq 3$
 1176 days, Fig. A1), so the limit of 14 days used by Griffin et al (2022b, a) is not needed. It is likely that clusters of 2
 1177 or 3 meteorologically distinct cyclonic systems (Mailier et al., 2006; Priestley et al., 2018; Vitolo et al., 2009)
 1178 combine within longer wind events. However, the focus here is on periods of disruption as they are
 1179 experienced.

1180
 1181 Precipitation events footprints are created exactly as for wind, except that the sum of precipitation (p) across
 1182 the duration of the event is retained at each location (i.e. instead of the maximum).

1183
 1184
 1185 *Table 2: Table of thresholds or limits used to define events. These thresholds used (i) in defining events and (ii) calculating severity indices*
 1186 *are not to be confused with the percentiles used to distinguish events of differing severity in the Results (e.g. 75th percentile of events*
 1187 *once they have been isolated and quantified in terms of a severity index).*

Threshold / Limit	Value
Percent of river network (q)	0.1%
Percent of GB land area (v, p)	0.1%
Extreme peak river flow (whole year), percentile of daily values.	99.5%

Extreme precipitation (Oct-Mar), percentile of daily values.	98.0%
Extreme daily 10 m max wind gust (Oct-Mar), percentile of daily values.	98.0%
Maximum length of event - from Griffin et al (2022a)	14 days

1188

1189 A.3 Event severity indices

1190

1191 Severity indices are ‘impact-based proxies’ for hazards such as flooding and wind extremes (Hillier and Dixon,
1192 2020), calibrated against and designed to reflected potential damage (Bloomfield et al., 2023; e.g., Christofides
1193 et al., 1992; Heneka and Ruck, 2008; Hillier and Dixon, 2020; Klawa and Ulbrich, 2003).

1194

1195 Storm Severity Indices (SSI) aim to condense the risk associated with a wind event into a single number
1196 incorporating factors thought to drive damage such as maximum wind gust (v), area affected and duration
1197 (e.g., Christofides et al., 1992; Dorland et al., 1999; Klawa and Ulbrich, 2003). Recently, following Klawa and
1198 Ulrich (2003) a form of SSI using v^3 in excess of a 98th percentile minimum threshold beneath which no
1199 damage occurs has become well-established as a norm (Bloomfield et al., 2023; e.g., Leckebusch et al., 2008;
1200 Osinski et al., 2016; Priestley et al., 2018). Rather than a region defined by a simple (e.g. circular) geometry
1201 (Manning et al., 2022, 2024), grid cells over land (e.g., Bloomfield et al., 2023; Pinto et al., 2012) are used to
1202 represent GB impact. For simplicity and to avoid a judgement linking value directly to population density (e.g.
1203 consider a wind farm), in contrast to Bloomfield et al. (2023), no population weighting is used. Thus, each
1204 event’s severity SSI(E) is given by Eq. (1):

1205

1206

$$SSI(E) = \sum_{i=1}^{N_i} \sum_{j=1}^{N_j} \left(\frac{v(E)_{i,j}}{v_{i,j}^{98}} - 1 \right)^3 \cdot I_{i,j}$$

1207

$$I_{i,j} = \begin{cases} 0 & \text{if } v(E)_{i,j} < v_{i,j}^{98} \\ 1 & \text{otherwise} \end{cases}$$

1208

1209 Two types of model have been used to approximate loss (l) or SSI, power-law ($l = k_1 v^\alpha$ for $v > v_{\text{thresh}}$) and
1210 exponential ($l = k_2 e^{\beta v}$), where k_1 , k_2 , α and β are constants, parameters to be determined by fitting to loss
1211 data. In general, the challenge is to approximate data where losses rise steeply above $\sim 32\text{ms}^{-1}$ (Christofides et
1212 al., 1992; Dorland et al., 1999; Heneka and Ruck, 2008). Using no threshold an exponential form, which can rise
1213 very abruptly, fits postcode district losses for 5 storms better than α of 2-4 (Dorland et al., 1999). With a
1214 threshold of $\sim 20\text{-}24\text{ms}^{-1}$ or the 98th percentile (e.g., Christofides et al., 1992; Klawa and Ulbrich, 2003) v^3 can
1215 fit losses for a storm (i.e. within 1-2 days) at district or national resolution, and allow modelling of district level

1216 historical losses (e.g., Pinto et al., 2012). This said, the 1999 storms sequence (Anatol, Lothar, Martin) showed
1217 losses above 24 ms^{-1} may on occasion rise more sharply for certain domains (i.e. $v^4 - v^5$ for Denmark,
1218 Germany)(MunichRe, 2002).

1219
1220 At a daily timescale a 98th percentile threshold (i.e. ~ 7 times per year) arises as, in practice, relatively little
1221 damage occurs below this level ($\sim 20 \text{ ms}^{-1}$) in the flat areas of UK and German (Klawka and Ulbrich, 2003;
1222 Palutikof and Skellern, 1991). Of course some places, such as mountains, are windier (Heneka et al., 2006; e.g.,
1223 Hewston and Dorling, 2011) but both nature (e.g. trees) and the built environment appear to adapt to this
1224 recurrence level. Klawka and Ulbrich (2003) illustratively note that winds at List (island of Sylt) exceed 20 ms^{-1} 1-
1225 in-5 days to no noticeable detriment, and building regulations (e.g. UK, Germany, Netherlands) require greater
1226 resilience in windier areas (e.g., Böllman and Jurksch, 1984; Chandler et al., 2001; Dorland et al., 1999; Hill et
1227 al., 2013). Whilst a higher percentile might be appropriate for higher frequency data (6-hourly, 99th) (Manning
1228 et al., 2024), damage on 2% of days (i.e. 98th percentile) is not wildly different from the number of UK storms,
1229 which are named (i.e. 7-8 per/year) when the Met Office believes it has '*potential to cause disruption or*
1230 *damage*' (Met Office, 2024).

1231
1232 Probabilistic models account for the uncertainty in how individual assets are damaged (Heneka et al., 2006;
1233 Heneka and Ruck, 2008), for instance using a power-law and replacing the threshold with a function describing
1234 the probability of damage (Pardowitz et al., 2016; Prahla et al., 2012). This better approximates losses in
1235 Germany across all 2004 wintertime days in 11 years (1997-2007), although the costliest days (~ 10 per year)
1236 are still adequately modelled using cubic excess-over-threshold approach with a 98th percentile (Prahla et al.,
1237 2015). Thus using Eq. (1) is appropriate as these 'extremes' are the focus of this paper, particularly as ranks
1238 rather than absolute SSI values are primarily evaluated. Moreover, sensitivity testing indicates limited
1239 sensitivity of patterns of correlation (e.g. spatial) to are largely choice of threshold (Hillier and Dixon, 2020),
1240 something borne out by the convergence of results for recent UK flood-wind research that have employed a
1241 spectrum of methodological choices (see Section 4.1).

1242
1243 Storm duration has been argued to influence losses (e.g., Christofides et al., 1992), but statistical studies have
1244 found that it does not improve models and may risk 'over-fitting' (Dorland et al., 1999), so in line with the
1245 Klawka and Ulbrich (2003) such potential influences (e.g. precipitation, duration) are not included here. We
1246 also note that v^3 is theoretically related to kinetic energy flux (e.g., Pinto et al., 2012) and to the dissipation of
1247 kinetic energy in the surface layers of a storm (Bister and Emanuel, 1998; Businger and Businger, 2001;
1248 Emanuel, 1998, 2005). However, we discount this as any justification for a cubic relationship between
1249 economic loss and v , other than perhaps as for the presence of non-linearity. Simply, for cubically increasing
1250 losses over a threshold (e.g., Christofides et al., 1992; Dorland et al., 1999) a cubic relationship that starts at
1251 zero velocity, as kinetic energy must, does not fit them well (Prahla et al., 2015).

1252

1253 Based on the form of SSI, Flood Severity Indices (FSI) have recently been developed (Bloomfield et al., 2023,
1254 2024). Only grid cells on the river network (e.g., Bloomfield et al., 2023) are used, again with no population
1255 weighting. Thus, each events' flood severity $FSI(E)$ is given by Eq. 2:

1256

1257

$$FSI(E) = \sum_{i=1}^{N_i} \sum_{j=1}^{N_j} \left(\frac{q(E)_{i,j}}{q_{i,j}^{99.5}} - 1 \right) \cdot I_{i,j}$$

1258

$$I_{i,j} = \begin{cases} 0 & \text{if } q(E)_{i,j} < q_{i,j}^{99.5} \\ 1 & \text{otherwise} \end{cases}$$

1259

1260 The 99.5th percentile is inherited, for consistency, from Griffin et al (2022a). It is largely arbitrary, intended to
1261 yield sufficient data points for statistical analysis (Bloomfield et al., 2023; Griffin et al., 2022b; Martius et al.,
1262 2016; Zhang et al., 2011). It is less than the 2-year return period 'rule of thumb' for bank-full discharge (i.e.
1263 99.9th percentile), although the work this derives from (Williams, 1978) is highly equivocal (i.e. 1-32 year range)
1264 due to factors such as basin characteristics, local climate and flood defences (Berghuijs et al., 2019; e.g., Tian et
1265 al., 2019). The cubic power is removed as it is not required with, as for SSI, justification of this functional form
1266 of FSI being through validation, replicating losses and capturing known floods (Bloomfield et al., 2023).
1267 Historical FSIs are highly correlated ($r = 0.74$, $p < 0.05$) with infrastructure loss data on an annual timescale, and
1268 FSI captures 28 of 34 wintertime floods (1980-2020) in the Chronology of British Hydrological Events (Black and
1269 Law, 2004). This said, lots of small FSI 'events' occur where no flooding was historically recorded. Also, without
1270 a threshold non-linearity (i.e. $SI \sim^5$) improves the fit of one proxy to losses (Hillier and Dixon, 2020), so debate
1271 on the form of FSI is expected to continue.

1272

1273 FSI as configured in Eq. 2 is suitable here as only the most extreme events are selected (i.e. >75th percentile of
1274 events). This is 5-6 high flows per year, comparable to the ~7 floods per year in commercial risk models (Hillier
1275 et al., 2024).

1276

1277 A Precipitation Severity Index (PSI) is used for consistency, despite severity perhaps being an incorrect term as
1278 rain itself rarely does damage directly (Manning et al., 2024). PSI is defined as for SSI, except that a cubic
1279 relationship is omitted as there is no justification for the additional complexity. $PSI(E)$ for each event is given by
1280 Eq. 3:

1281

1282

$$PSI(E) = \sum_{i=1}^{N_i} \sum_{j=1}^{N_j} \left(\frac{p(E)_{i,j}}{p_{i,j}^{98}} - 1 \right) \cdot I_{i,j}$$

$$I_{i,j} = \begin{cases} 0 & \text{if } p(E)_{i,j} < p_{i,j}^{98} \\ 1 & \text{otherwise} \end{cases}$$

A.4 Description of Event Sets

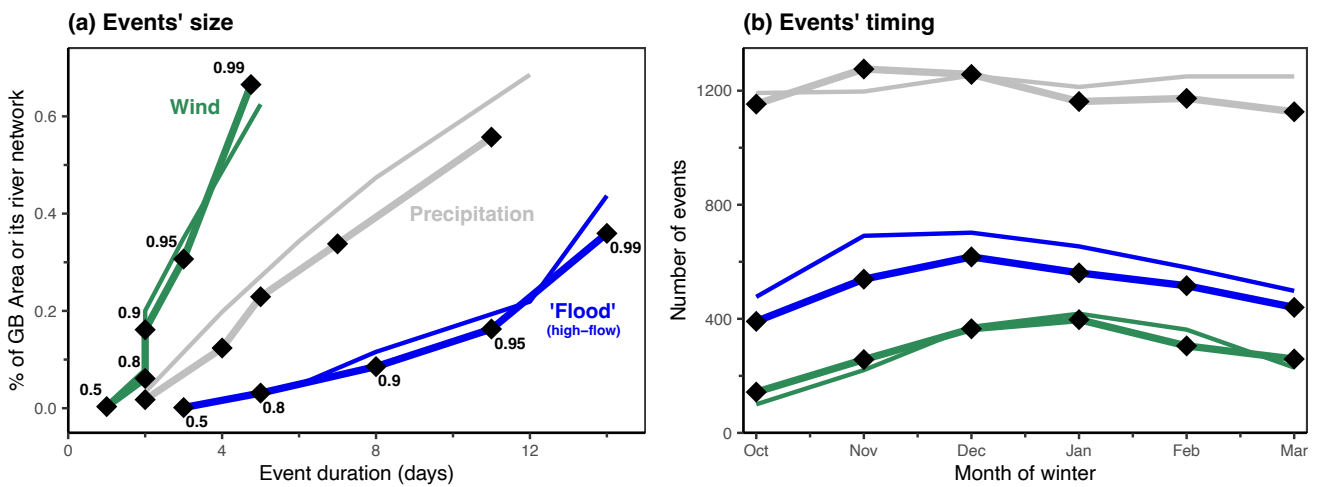

A set of high-flows events (Griffin et al., 2022b, a) has been created for the UKCP18r 12-member perturbed parameter ensemble (PPE) of the Hadley Centre 12km Regional Climate Model (RCM) (Murphy et al., 2018; Tucker, et al., 2022). Thus, to mirror this, UKCP18r was used to generate wind ($n = 3,427$) and precipitation ($n = 14,502$) events across mainland Great Britain for baseline (winters 1981-1999) and future (winters 2061-2079) time-slices. The wind event set is broadly aligned to other such sets in its construction methods (Lockwood et al., 2022; Osinski et al., 2016; Roberts et al., 2014), and the data been validated for the purposes of examining hazard co-occurrence (Appendix A.1). Summary metrics are created for these event footprints (total area, duration, SI) and assigned to a single date t_{max} , the individual day when the greatest number of grid cells exceed the set threshold.

First consider the size and number of events at the present time. There are 7-8 wind events per year in 1981-1999 on average, each tending to affect a large area (i.e. up to 60% of GB) but be relatively short-lived (< 5-day). This contrasts longer-duration yet more localized fluvial flooding (Fig. A1a). These properties match what is typical of these event types (e.g. Mitchell-Wallace et al., 2017). No wind event ever exceeds 8 days, so the limit of 14 days used by Griffin et al (2022b, a) is not needed. Extreme precipitation is more common than wind with 31-33 events per year, as is flooding at 13-16 events per year.

The relative frequency of events is statistically dictated, depending upon the size of each phenomenon and the parameters (e.g. thresholds) used to extract events. The spatial length-scale of correlation (i.e. floods are typically smaller) increases their number, counteracted somewhat by them lasting longer and the higher percentile. Imagine an idealised scenario wherein windstorms hit the whole UK, whilst floods impact 10% of its area (e.g. in 10 uncorrelated areas). Now, for a 98th daily percentile, every 1 in 50 days all WS points will peak at the same time giving 1 event. For flood, this will happen separately in the 10 areas, giving 10 events. The higher percentile (i.e. 99.5th vs 98th) used for flooding will reduce this by four times, giving 2.5 events in 50 days. Also, by lasting longer, the flood events might merge more readily, reducing their number.

The events in 2061-2079 have some differences to 1981-1999. Fig. A1 echoes the finding of Griffin et al (2022b) that flooding is expected to be more frequent (+18% here) and heavier tailed with larger extreme events (Fig. A1a) and somewhat more seasonal with a focus in mid-winter (DJF), but also identifies a potential shift to a slightly earlier peak in future (Fig. A1b). Considering all events, neither precipitation nor wind events increase in number significantly into the future (t -test between means of ensemble members), and echoes the

1318 muted changes in climatology (e.g., Manning et al., 2022, 2024). It differs, however, from true extremes are
 1319 examined in papers (Bloomfield et al., 2023) or the main text. Illustratively, increases for Oct-Mar are +59% for
 1320 the 75th percentile of FSI, +91% for the 95th percentile of FSI in Fig. 6a,d, both of which are significant ($p < 0.01$).
 1321
 1322 Only the top quarter of events defined are focussed upon (i.e. most severe quarter, >75th percentile). For wind
 1323 events there are 7-8 per year in total, which roughly reflects the Met Office's named storms 2015-2023
 1324 (7.4/yr)(Met Office, 2024). Thus, 1-2 per year are focussed upon, comparable to the ~3 per year used in
 1325 insurance industry risk modelling (Hillier et al., 2024). There are 15 high flow events per year, and taking the
 1326 top quarter gives ~4 notable high-flow events, comparable to the 6-7 floods per year in a commercial model
 1327 (Hillier et al., 2024).
 1328

1329
 1330
 1331 Fig. A1: (a) Size and duration of events created for Wind, Precipitation and Flood. 'Flood' events are high-flow events created by Griffin
 1332 et al (2023). Percentiles are shown from 50th to 99th, calculated separately for duration and area (i.e. this is not a joint distribution).
 1333 Present day (thick lines) and future (thin lines) are similar if all the events are considered. (b) Seasonality of the events.

1334 Appendix B: Additional statistics

1335 B.1 For increased concentration of events and episodes in midwinter

1336
 1337
 1338 In Section 3.2, from Fig. 6, claims are made about an increased concentration of flooding, extreme wind and
 1339 episodes containing both in midwinter. Table 2 Table presents a statistical analysis of the prevalence of events
 1340 and episodes between December and February (DJF) as compared to the whole Oct-Mar winter. A Binomial
 1341 distribution is used, i.e. $X \sim B(t, f)$, with t trials and a chance of success f . Then using the cumulative Binomial
 1342 distribution, the chance of the observed number of events (i.e. n in DJF) or more arising through random
 1343 selection within in a stated number of trials (i.e. n in whole winter) can be assessed. First, the hypothesis that
 1344
 1345

1346 there are more events in DJF is tested. Here the null hypothesis is that the real distribution in time is equal
 1347 between DJF and the three other months, i.e. $f = 0.5$. With $p < 0.05$ in all cases (Table 2), the research
 1348 hypothesis that events and episodes are concentrated in midwinter can be accepted. Secondly, the hypothesis
 1349 that levels of concentration in midwinter are increasing from 1981-1999 to 2061-2079 is tested. Here, f is set
 1350 by the fraction of events in DJF in the present day. In add cases except lower-percentile (75th) for 3-day
 1351 flooding, events and episodes are significantly ($p < 0.05$) more concentrated in midwinter (i.e. DJF).

1352
 1353
 1354
 1355

Table 2: Table presenting a statistical analysis of the prevalence of events and episodes between December and February (DJF) as compared to the whole Oct-Mar winter.

				Total n	DJF n	Fraction (f) DJF	p (f=0.5)	p (f= present day)
