

1 August 8th, 2024,

2 Dear EarthArXiv Editors:

3 On behalf of myself and my co-authors, I submit our original research article “The Origin of Forearc
4 Depressions” for consideration for publication as a non-peer reviewed preprint in EarthArXiv. The
5 manuscript was submitted to Geology and was rejected, and is now being edited for submission to Terra
6 Nova. The attached manuscript reflects that of our submission to Geology.

7 Please address all correspondence regarding this manuscript to me at chuqiaoh@sfu.ca.

8 Thank you for your consideration.

9 Sincerely,

10 Mr. Chuqiao Huang (chuqiaoh@sfu.ca)

11 Ph.D. Candidate, Simon Fraser University

12

27 **ABSTRACT**

28 Forearc depressions form over continental subduction zones with young, slowly subducting slabs and
29 thick trench fills. They are bound seaward by a coast range and landward by a volcanic arc such that
30 subsidence in forearc depressions occurs between orogens and in areas characterized by plate
31 convergence. We propose a model for forearc depression formation based on geophysical and seismic
32 data from four circum-Pacific subduction zones. Coast range crests coincide with >100 mGal gravity
33 anomalies, which are attributed to underplated material and indicate that underplating drives coast range
34 uplift. Coast range crests are situated near the down-dip termini of megathrust earthquake rupture zones,
35 showing that coast ranges overlie where subduction interface sliding behaviour transitions from frictional
36 to semi-frictional. This transition causes subduction interface shear stress to begin decreasing with depth
37 and triggers underplating as shear stress becomes insufficient to drag buoyant material deeper. Forearc
38 depressions are situated landward of inter-plate seismic phenomena, indicating they overlie the hydrated
39 forearc mantle. Forearc depressions form as counter-flexural basins over the hydrated forearc mantle; in
40 this position the upper plate crust is not supported by the flexurally rigid slab and can bend downwards.
41 Forearc depressions do not form over old slabs because old slabs do not exceed the temperature threshold
42 for semi-frictional sliding prior to intersecting the mantle wedge corner. Fast convergence rates and thin
43 trench fills promote subduction erosion along the subduction interface, thereby prohibiting the formation
44 of coast ranges, and by extension, forearc depressions.

45 INTRODUCTION

46 Forearc depressions (Fig. 1) are a type of forearc basin and form over continental subduction
47 zones with young (typically <30 Ma), slowly subducting (<65 mm yr⁻¹) slabs and thick trench sediment
48 fills (>2.5 km). Forearc depressions entirely overlie the upper plate and are bound seaward by a coast
49 range and landward by a volcanic arc. Modern examples include the Seto Inland Sea of the Nankai
50 subduction zone in Japan; the Kenai Lowlands–Cook Inlet–Sheliklof Strait of the Alaskan subduction
51 zone in USA; the Salish–Puget–Willamette Lowland of the Cascadia subduction zone in Canada and
52 USA; and the Central Depression of the south-central Chilean subduction zone (Fig. 2).

53 Forearc depressions are narrow (typically 75 km trench-orthogonal width) with km-scale thick
54 basin fills and are sandwiched between areas of km-scale uplift. Their formation is challenging to explain
55 as proposed hypotheses must address how forearc depressions form between orogens and in regions
56 characterized by plate convergence. Recently, Menant et al. (2019, 2020) used computer modelling to
57 hypothesize that fluid escape from the subduction channel increases subduction interface shear stress,
58 which triggers underplating. Underplating drives coast range uplift, which then causes downwards
59 counter-flexure of the upper plate crust and forearc depression formation. Here, we revise the model of
60 Menant et al. (2019, 2020) using empirical data to show that changes in subduction interface rheology
61 decreases shear stress and triggers underplating, and that a young, slowly subducting slab and thick trench
62 cover are required for this process. We also show that forearc depressions are situated over the hydrated
63 forearc mantle and cannot form seaward of the mantle wedge corner. For clarity, we use ‘coast range’ to
64 refer to forearc highs that form through underplating and not through other mechanisms, such as over-
65 thrusting of the accretionary prism (e.g., the Sunda Subduction Zone; Mukti et al., 2021).

66 Subduction interface shear stress varies with depth and as a function of sliding behaviour. In warm
67 subduction zones, which includes those with young slabs, the subduction interface can be divided into

68 frictional, semi-frictional, and stable sliding domains (Fig. 1) and the locations of these domains can be
69 inferred by their differing seismic behaviours. Shear stress peaks and begins to decrease in the transition
70 between the frictional and semi-frictional domains (Gao and Wang, 2017).

71 In the frictional domain (Fig. 1), shear stress increases with depth (Gao and Wang, 2017) because
72 frictional strength increases with normal stress. The frictional domain defines the seismogenic zone
73 wherein megathrust earthquakes nucleate and propagate. The up-dip limit (seaward and shallower) of the
74 frictional domain depends on subduction interface temperature and mineralogy and can extend to the
75 seafloor (Roesner et al., 2020; Stanislawski et al., 2022). The down-dip limit (landward and deeper) of
76 the frictional domain corresponds to where the subduction interface exceeds 300–400 °C whereupon
77 quartz and feldspar begin to exhibit crystalline plasticity (Hyndman et al., 1997; Oleskevich et al., 1999).

78 In the semi-frictional domain (Fig. 1), shear stress decreases with depth (Gao and Wang, 2017)
79 because ductile strength decreases with temperature. Megathrust earthquakes cannot propagate into the
80 semi-frictional domain due to its rate-strengthening nature, and viscous processes cause slow-slip events
81 (Schwartz and Rokosky, 2007). Very young slabs (<20 Ma) additionally experience metamorphic
82 dehydration reactions at shallow depths (<50 km; Condit et al., 2020); this releases slab fluids that are
83 trapped beneath an impermeable subduction interface. Trapped fluids greatly lower shear stress (Gao and
84 Wang, 2017) and lowered shear stress generates episodic tremor and slip that clusters around the mantle
85 wedge corner (Shelly et al., 2006; Calvert et al., 2020).

86 In the stable-sliding domain (Fig. 1), shear stress is low and the subduction interface is aseismic.
87 The up-dip limit of the stable-sliding domain is where the slab contacts the hydrated forearc mantle and
88 free water is limited. Antigorite, the high pressure form of serpentinite (Schwartz et al., 2013), deforms
89 by viscous processes at inter-seismic strain rates (Tulley et al., 2022) and cannot accumulate the stress
90 required to initiate megathrust earthquakes.

91 Subduction interface shear stress is determined using the seismic behaviour of different sliding
92 domains, and hence, we examine geophysical and seismic data from subduction zones that host forearc
93 depressions. For each system, we compile data on topography and bathymetry, convergence rates, slab
94 ages, free-air gravitational anomalies, megathrust earthquake epicenter and rupture zones, tremor
95 epicenters, and top-of-slab depth (Supplementary Data File 1). We map and interpret these data to
96 establish how underplating, subduction interface shear stress distribution, and the location of the mantle
97 wedge corner drive coast range and forearc depression formation. We also show why young, slowly
98 subducting slabs and thick trench cover are required for coast range and forearc depression formation.

99 **CHARACTERIZATION OF FOREARC DEPRESSIONS**

100 In the Menant et al. (2019, 2020) model, underplating uplifts the overlying crust and generates a
101 coast range. Gravity anomalies increase towards the coast range crest to >100 mGal, and increasing
102 gravity anomalies are attributed to underplated material (Bassett and Watts, 2015) (Figs. 3A–D).
103 Specifically, underplating causes uncompensated crustal thickening, which increases free-air gravity
104 anomalies. Increasing gravity anomalies associated with coast ranges coincide with km-scale reflector
105 bands that are interpreted as underplated material (Calvert et al., 2006; Kimura et al., 2010; Scholl, 2021;
106 Delph et al., 2021).

107 Coast ranges also overlie where subduction interface shear stress begins to decrease with depth,
108 which is evident in the position of coast range topographic crests near the down-dip termini of megathrust
109 earthquake rupture zones (Figs. 3E–H). In warm subduction zones, megathrust earthquakes only
110 propagate in the frictional domain of the subduction interface (Fig. 1) and rupture zones terminate in the
111 transition between the frictional and semi-frictional domains. This transition is also where shear stress
112 changes from increasing with depth to decreasing with depth. There is no direct evidence from Cascadia
113 that shows the coast range overlying the down-dip termini of megathrust earthquake rupture zones

114 because the last megathrust earthquake occurred prior to modern record keeping (in 1700). However,
115 geodetically inferred interseismic locking models for Cascadia predict that subduction interface locking
116 (i.e., the predicted megathrust earthquake rupture zone) decreases to <10% beneath Cascadia's coast
117 range (Li et al., 2018; Lindsey et al., 2021), which is consistent with a transition from frictional to semi-
118 frictional sliding along the subduction interface.

119 The location of coast range topographic crests over where shear stress begins decreasing with
120 depth indicates that decreasing shear stress triggers the underplating necessary for coast range uplift.
121 Underplating occurs because shear stress becomes insufficient to drag buoyant material within the
122 subduction interface deeper.

123 All forearc depressions are situated landward of inter-plate seismic activity, showing they are
124 situated landward of the mantle wedge corner (Figs. 3E–H). In warm subduction zones, megathrust
125 earthquakes only propagate within the frictional sliding domain, which only exists where the slab is
126 beneath the upper plate crust and not the mantle (Fig. 1). As well, Nankai (Shelly et al., 2006) and
127 Cascadia (Calvert et al., 2020) experience episodic tremor and slip (Figs. 3E and G), and tremor
128 epicenters cluster around the mantle wedge corner (Fig. 1). The distribution of both megathrust
129 earthquake rupture zones and tremors seaward of forearc depressions show that all forearc depressions are
130 situated landward of the mantle wedge corner.

131 Underplating causes the overlying crust to flex upwards (Menant et al., 2020) and this upwards
132 flexure must be compensated by downwards flexure elsewhere. This cannot occur seaward of the mantle
133 wedge corner as the upper plate crust is supported through direct contact with the flexurally rigid slab.
134 Landward of the mantle wedge corner, the upper plate crust is no longer supported by physical contact
135 with the slab and so it can flex downwards to form the forearc depression.

136

137 The transition from frictional to semi-frictional sliding and the associated decrease in shear stress
138 that triggers underplating requires a young slab (<30 Ma; Fig. 2). Old slabs do not reach the temperature
139 threshold for transition between frictional and semi-frictional sliding prior to intersecting the mantle
140 wedge corner. As well, old slabs do not experience substantial metamorphic dehydration until they are
141 beneath the arc (Condit et al., 2020), which leads to a dry, antigorite-poor forearc mantle (Abers et al.,
142 2017; Wang et al., 2022). Consequently, old slabs are characterized by a single frictional domain wherein
143 shear stress increases with depth well into the forearc mantle. Old slabs also exhibit different seismic
144 behaviours: without a semi-frictional domain to resist the propagation of megathrust earthquakes
145 (Schwartz and Rokosky, 2007), rupture zones can extend into the hydrated forearc mantle (Brantut et al.,
146 2016). The exception to the relationship between slab age and subduction interface rheology described
147 above is Alaska, where the Pacific Plate is 35–50 Ma at the trench (Fig. 2B). The Pacific slab undergoes
148 flat subduction for 200–300 km over which it heats and exceeds 400 °C prior to intersecting the mantle
149 wedge corner (Qu et al., 2022).

150 A thick trench cover (>2.5 km) is required for coast range uplift through underplating because
151 trench sediments ultimately become the primary underplated material. For example, in the Central
152 American Subduction Zone, the subducting Cocos Plate is 0–25 Ma at the trench. The subduction zone
153 experiences SSEs and ETS (Baba et al., 2021), which shows the existence of a semi-frictional domain.
154 However, neither a coast range nor forearc depression are developed, and instead, a single, broad forearc
155 basin stretches from the shoreline to the trench. This is attributed to thin trench sediment cover (<0.5 km;
156 Clift and Vannucchi, 2004), which provides insufficient material to underplate and generate a coast range.
157 In contrast, subduction zones that host forearc depressions possess thick trench sediment covers (2.5–3.5
158 km; Clift and Vannucchi, 2004) which provide sufficient material for underplating.

159 Finally, a slow subduction rate ($<65 \text{ mm yr}^{-1}$; Fig. 2) is required for forearc depression formation.
160 At faster convergence rates, tectonic erosion dominates along the subduction interface (Clift and
161 Vannucchi, 2004) and underplating is suppressed; this inhibits the formation of a coast range.

162 **FORMATION OF FOREARC DEPRESSIONS**

163 Subduction zones with forearc depressions include an additional forearc basin over the
164 accretionary prism (Fig. 4). However, barring Nankai, for which subduction initiated recently (15 Ma;
165 Moreno et al., 2023), all subduction zones investigated here formerly comprised a single forearc basin
166 that stretched from the coastline to the trench. This is indicated by older strata within forearc depressions
167 that correlate to coeval strata over and/or seaward of the coast range (England and Bustin, 1998; Encinas
168 et al., 2012; LePain et al., 2014; Scanlon et al., 2021; Darin et al., 2022). For example, the Georgia Basin
169 is the northern-most forearc depression of Cascadia, and its basal succession is the Nanaimo Group, a >3
170 km thick succession of primarily Upper Cretaceous strata (England and Bustin, 1998; Giroto et al.,
171 2024). The Nanaimo Group is covered by >3 km of Cenozoic strata in the Georgia Basin; however,
172 Nanaimo Group strata, including trench orthogonal-oriented deep-marine turbidites, are exposed on
173 Vancouver Island, which is the associated coast range. This distribution of strata indicates that for much
174 of Nanaimo Group deposition, no trench-parallel topographic barrier existed, and sedimentation occurred
175 in a single, broad forearc basin. Based on this, we propose the following model for the formation of
176 forearc depressions (Fig. 4):

177 1) Prior to forearc depression formation, a single forearc basin stretches from the shoreline to the
178 trench and is dominated by deep-marine depositional systems and trench-orthogonal drainage
179 (e.g., south Cascadia in the Eocene; Santra et al., 2013). Coast range uplift is suppressed by
180 unsuitable subduction parameters such as an old slab, thin trench sediment cover, and/or high
181 convergence rate (Fig. 4A).

- 182 2) Increases in trench sedimentation, decreases in slab age, and/or decreases in convergence rate
183 initiate underplating. The accretionary prism grows, leading the frictional domain to shift seaward
184 as a thick blanket of sediment insulates the slab. Underplating focuses over the transition between
185 the frictional and semi-frictional domains, which uplifts the overlying crust to generate a coast
186 range. The coast range divides the overlying forearc basin in two (Fig. 4B).
- 187 3) Repeated underplating leads to further coast range uplift. Forearc strata overlying the coast range
188 are uplifted, eroded, and re-incorporated into the flanking forearc basins (e.g., south Cascadia in
189 the Oligocene; Darin et al., 2022). Flexural counter bending occurs over the hydrated forearc
190 mantle generating a forearc depression (Menant et al., 2020). Sedimentation in the forearc
191 depression is dominated by continental- and shallow-marine depositional systems and trench-
192 parallel drainage (Fig. 4C).

 314 stress (τ) distribution along the subduction interface and predicted inter-plate sliding behaviour. Expected
 315 locations of inter-plate seismic events are labelled on the x-axis. Abbreviations: SSEs – slow slip events;
 316 ETS – episodic tremor and slip. **B)** Predicted free-air gravity anomaly field of the subduction zone. **C)**
 317 Major tectonic elements of the subduction zone. No vertical exaggeration.

318

319

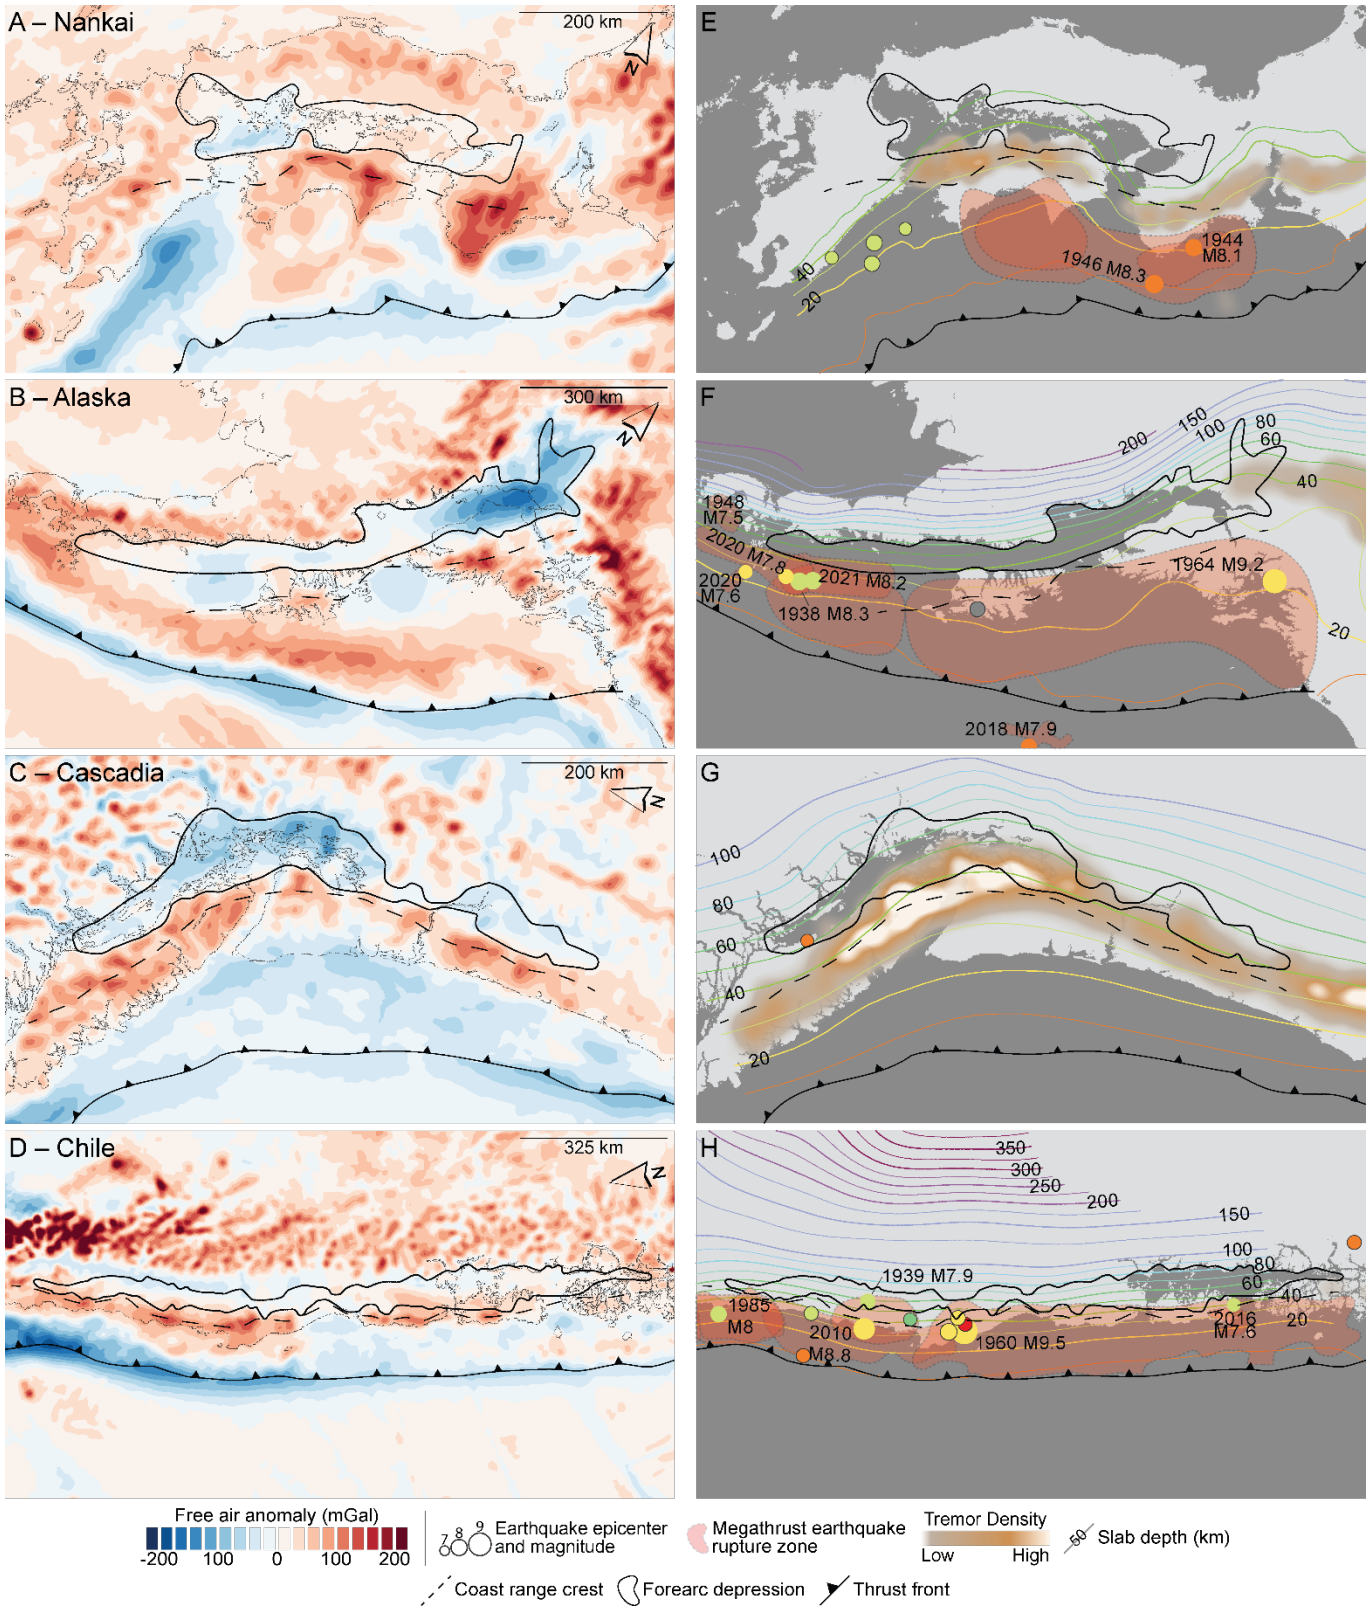

320

321

322

323

Figure 2. General subduction parameters of subduction zones with forearc depressions. Data shown include topography/bathymetry, convergence rate with respect to a stable upper plate, oceanic plate isochrons, Holocene volcanoes, coast range topographic crest, forearc depression boundary, and subduction thrust front. No oceanic plate isochrons are present for Cascadia because the Juan de Fuca oceanic plate is younger than 10 Ma everywhere.

325 **Figure 3.** Geophysical and seismic data from subduction zones with forearc depressions. All maps
326 include coast range topographic crest, forearc depression boundary, and subduction thrust front. **A–D)**
327 Free-air gravity anomalies, scaled to ± 200 mGal. **E – H)** Seismic activity. Data show include megathrust
328 earthquake magnitudes, epicenters, and rupture zones, tremor densities, and top-of-slab depth. Megathrust
329 earthquake epicenters and top-of-slab depth share the same colour scheme, which indicates depth. For
330 megathrust earthquake epicenters, no circle outline means its rupture zone is depicted and an outline
331 means it is not.
332

335 **Figure 4.** Schematic for the formation of a forearc depression. Time steps A–C are described in the text.
 336 Each schematic depicts the shear stress (τ) distribution along the subduction interface and predicted inter-
 337 plate sliding behaviour, and tectonic elements of the subduction zone. Legend and scale are same as
 338 figure 1. No vertical exaggeration.

339 **SUPPLEMENTARY FILE 1: DATA SOURCES**

340 Our study compiles and interprets publicly available data. We focus on four subduction zones
341 globally that host forearc depressions: Nankai, Alaska, Cascadia, and Chile. For each subduction zone,
342 we assemble and interpret three datasets: 1) general subduction parameters, 2) gravity, and 3) seismic.

343 **GENERAL SUBDUCTION PARAMETERS**

344 The general subduction parameters dataset comprises topographic and bathymetric data, forearc
345 depression boundaries, Holocene volcanic centers, oceanic plate isochrons, and plate convergence rates.
346 Topographic and bathymetric data are derived from the General Bathymetric Chart of the Oceans project
347 (Mayer et al., 2018). Coast ranges are defined by tracing a line through the topographic crest of each
348 coast range, and forearc depression boundaries are defined by tracing the 200m topographic contour.
349 Holocene volcanic data is derived from the Volcanoes of the World Database (Venzke, 2023), and
350 oceanic plate isochrons are derived from Seton et al., 2020. Plate convergence vectors are based on plate
351 motions calculated by the Global Strain Rate Model v2.1 (Kreemer et al., 2014) and are defined with
352 respect to a stable upper plate: for Nankai, the Philippine Sea Plate subducts beneath the stable Amur
353 Plate; for Alaska, the Pacific Plate subducts beneath the stable North American Plate; for Cascadia, the
354 Juan de Fuca Plate subducts beneath the stable North American Plate; and for Chile, the Nazca Plate
355 subducts beneath the stable South American Plate.

356 **GRAVITY DATA**

357 Gravity data is derived from the satellite free-air gravity model of Sandwell et al. (2014).
358 Sandwell et al. (2014) provide data in a 1 arc-minute by 1 arc-minute grid. We use kriging to generate our
359 free-air gravity anomaly map. We normalize all gravity data to ± 200 mGal because these values cover the
360 full range of gravity anomalies from the trench to the volcanic arcs of the subduction zones investigated

361 herein. While some areas, such as the Bonin trench and volcanic arc (Fig. 3A), have anomalies more than
362 ± 300 mGal, these higher values are not portrayed because they are not relevant to this study.

363 **SEISMIC DATA**

364 Seismic data includes megathrust earthquake epicenters and rupture zones, tremor epicenters, and
365 top-of-slab depth data. Megathrust earthquake epicenters are derived from the USGS earthquake catalog
366 for all earthquakes that: 1) occurred between 1900 and 2023, 2) exceeded 7.5 magnitude; and, 3) were
367 shallower than 70 km. These search parameters filter out most other earthquake types that occur near
368 subduction zones, such as intra-slab and intra-crust earthquakes. Megathrust rupture zone data are
369 compiled from a variety of sources. For Nankai, rupture zones are calculated by Ando (1975). For Alaska,
370 rupture zones are derived from the Alaska Earthquake Center. For Chile, rupture zones are compiled from
371 Kelleher (1972), Sparkes et al. (2010), and Hicks et al. (2014).

372 Tremor data is compiled from multiple sources. For Nankai, tremor data is from the World
373 Tremor Database generated by Idehara et al. (2014). For Alaska, tremors are from Wech (2016). For
374 Cascadia, tremors are derived from the Pacific Northwest Seismic Network's tremor catalog (Wech,
375 2021) for all events occurring between August 6, 2009 and September 4, 2023. For Chile, tremor data are
376 derived from the World Tremor Database, which combines data from Idehara et al. (2014), Yabe and Ide
377 (2014), and Pastén-Araya et al. (2022) . Slab depth data are from Nakanishi et al. (2018) for Nankai,
378 McCrory et al. (2012) for Cascadia, and the Slab 2.0 model of Hayes et al. (2018) for Alaska and Chile.
