ABSTRACT

Certain Mg-suite samples display enrichment in incompatible elements, likely resulting from the assimilation of the material that crystallized at the very late stages of magma ocean (ur-KREEP). This study uses trace element analyses of plagioclase separates from sample 76535 to estimate the Rare Earth Element (REE) concentration of the Mg-suite parental liquid and assess the extent of contribution from ur-KREEP. Thirty-three trace elements, including REEs, were measured in the separates and the measured REEs reflect magmatic conditions being free from subsolidus alteration. The Mg-suite parental liquid was estimated using these REE data as targets for a Python-based forward model which employs a RhyoliteMELTS-defined liquid line of descent. The estimated parental liquid shows REE enrichments of 200 times chondritic levels for Light REEs and 20 times for Heavy REEs. Mixing models between the REE compositions of a potential Mg-suite primary liquid and modeled ur-KREEP indicate that 30-50% assimilation of ur-KREEP is required to reproduce the observed REE concentrations in the Mg-suite parental liquid. We demonstrate an approach to determine the petrogenesis of a sample by characterizing a very limited quantity of grains, in an effort to maximize the scientific output from current and future returned samples such as Artemis.

INTRODUCTION

The Mg-suite is a series of lunar highlands samples composed predominantly of anorthositic lithologies, which are chemically distinct from other lunar highlands terranes (Warner et al., 1976). The Mg-suite is characterized by an alkali content of 0.05 wt% K₂O, highly magnesian olivine (Fo > 80, where Fo = Mg/[Mg + Fe]), and highly calcic plagioclase (An > 90, where An = Ca / [Ca + Na + K]) (Dymek et al., 1975; Gooley et al., 1974, Snyder et al., 1999). Mg-suite samples are enriched in incompatible trace elements (Haskin et al., 1974; Gooley et al., 1974; Dymek et al., 1975) which has been designated a KREEP signature because of enrichments in potassium, rare-earth elements (REEs), and phosphorus. Explanations for the source of this signature have suggested the assimilation of the residual liquid created by 99% crystallization of the lunar magma ocean called ur-KREEP (Warren 1986; Hess 1994; Papike et al., 1998; Shervais and McGee, 1998; Shearer and Papike, 2005; Longhi et al., 2010; Elardo et al., 2012).

Aside from the Mg-suite, Mg-rich cumulates have also been identified in lunar meteorites (Treiman et al., 2010; Yamaguchi et al., 2010; Roberts et al., 2019; Gross et al., 2020; Cao et al., 2021; Hulsey et al., 2024; He et al., 2024) and in the Chang'e 5 samples (He et al., 2024). These

47 additional Mg-rich samples may be cogenetic with the Mg-suite. However, some are KREEP-
48 poor compared to the Mg-suite (Treiman et al., 2010; He et al., 2024). The absence of a KREEP
49 signature in these Mg-rich cumulates may be linked to lunar crustal dichotomy. Remote sensing
50 data restricts enrichments of radioactive elements associated with ur-KREEP to the nearside
51 Procellarum KREEP Terrane (PKT) and the farside South Pole-Aitken Terrane (SPAT)
52 (Lawrence et al., 2000; Metzger et al., 1973, 1977; Jolliff et al., 2000; Martinot et al., 2020), while
53 likely exposures of Mg-rich cumulates have been identified across the lunar surface (Lucey and
54 Cahill, 2009; Klima et al., 2011; Jolliff et al., 2000; Taylor, 2009; Prissel et al., 2014a; Shearer et
55 al., 2015; Hulsey et al., 2024). Much of these identified Mg-rich exposures lay outside the PKT,
56 and SPAT, and may therefore be the source of the KREEP-poor Mg-rich cumulate samples.
57 Additional petrogenetic differences may also exist between KREEP-rich and KREEP-poor Mg-
58 rich samples, as suggested by James and Flohr (1983), Treiman and Gross (2015), Prissel et al.
59 (2016), and Gross et al. (2020). The complex characteristics of Mg-suite samples have led to
60 varying models for their formation. Shearer et al. (2015) provided a comprehensive summary of
61 models for Mg-suite petrogenesis which include: (1) impact melting and differentiation (Taylor
62 et al., 1993; Hess 1994; McKay et al., 1979), (2) co-magmatism with the primary FAN (Ferroan
63 Anorthosite) crust (Wood, 1975; Longhi and Boudreau, 1979; McCallum, 1983) (3) post Lunar
64 Magma Ocean (LMO) KREEP remelting and remobilization (Hess et al., 1978; Hess, 1989;
65 Snyder et al., 1995) (4) decompression or radioactive decay induced melting of early LMO
66 cumulates (Warren and Wasson, 1977; James and Flohr, 1983; Warren, 1986; Papike et al.,
67 1994; Papike et al., 1996; Snyder et al., 1992), and (5) melting of a hybridized LMO cumulate
68 and KREEP lithology in either the upper or lower mantle (Shearer et al., 2006; Shearer and
69 Floss, 2000; Shearer and Papike, 1999, 2005; Elardo et al., 2012).

70 Shearer et al. (2015) present several lines of evidence opposing the impact melting model,
71 including the required mass balance between the impactor and the crust, the depth of Mg-suite
72 formation (30-50 km) in comparison to common buried impact melt sheet depths, and the pre-
73 Nectarian ages of Mg-suite samples which are older than most large near-side craters.
74 Consequently, models that incorporate decompression melting of rising cumulates as the source
75 of the primary Mg-suite parental liquid, which subsequently interacts with ur-KREEP, forming
76 the Mg-suite parental liquid, have gained favor in the lunar science community. This model can
77 effectively reproduce the mineralogy of the Mg-suite and their trace element enrichments in
78 Apollo Mg-suite samples (Elkins-Tanton et al., 2002; Laneuville et al., 2013). However, the
79 necessity of an ur-KREEP contribution to Mg-suite petrogenesis has been questioned (e.g.,
80 Shearer et al., 2015; Elardo et al., 2020), and the nature of the temporal relationship between the
81 Mg-suite, ur-KREEP, and FAN needs to be resolved.

82 To complete the objectives of this work and confirm a model for Mg-suite petrogenesis, it
83 is essential to first reconcile its chronological relationship with FAN and ur-KREEP. While
84 extrapolations from multiple geochronometers (Pb-Pb, Ar-Ar, Rb-Sr, and Sm-Nd) suggest that
85 the Mg-suite is contemporaneous with FAN at 4359 ± 9 Ma (Borg et al., 2020) and ur-KREEP at
86 4368 ± 29 Ma (Gaffney and Borg, 2014; Snape et al., 2016; and Maurice et al., 2020), Nelson et
87 al. (2021) demonstrated through diffusion chronology that Mg-suite plutonic bodies initially
88 cooled more rapidly, placing their formation around 4.33 Ga. Ages consistent with this younger
89 age are common in Mg-suite samples, having been observed in samples 78236 (4333 ± 59 Ma;
90 Edmunson et al., 2009), 67667 (4349 ± 31 Ma and 4368 ± 67 Ma; Borg et al., 2020), and 77215
91 (4368 ± 42 Ma; Zhang et al., 2021). This chronological data, clustered around 4.33-4.35 Ga,

92 suggests that the Mg-suite represents a pulse of magmatism occurring approximately 20 Ma after
93 the segregation of FAN.

94 To elucidate the mechanisms behind the KREEP signature in the Mg-suite, further analyses
95 of Mg-suite samples are required. The results of these analyses can then be used to model trace
96 element concentrations in their parental liquids. Such an exercise might focus on REEs, given
97 their sensitivity to magmatic processes and well-constrained partitioning behavior in lunar
98 magmas. REEs also function as quantitative tracers of crystallization and fractionation processes
99 (Hess, 1989) which are used to explore the petrogenesis of the parental liquid.

100 The first objective of this work is to re-analyze the trace elements in plagioclase from Mg-
101 suite sample 76535-11 using microanalytical techniques. Sample 76535 was selected for this
102 work as it is considered the most pristine Mg-suite sample (Warren, 1993). Previous studies
103 (Haskin et al., 1974; Borg et al., 2017) have reported trace element concentrations for 76535
104 through solution-based analyses of mineral separates. Haskin et al. (1974) measured REEs in
105 grain separates from 76535-21 and 76535-22 through isotope dilution. Borg et al. (2017)
106 analyzed REE grain separates of 76535-11 using inductively coupled plasma mass spectrometry
107 (ICP-MS).

108 Analyses of bulk mineral material limit observations of inter- and intra-grain heterogeneity.
109 Plagioclase from 76535 (Nelson et al., 2021) and other Mg-suite samples (Shervais and McGee,
110 1998) contain notable albitic rims, which may be REE-rich, skewing the analysis. To address
111 these issues, we utilized three microanalytical techniques to measure inter- and intra-grain
112 chemistries: electron probe microanalysis (EPMA), secondary ion mass spectrometry (SIMS),
113 and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Thirty-three
114 trace and minor elements were measured in this study, including but not limited to major
115 elements, first-row transition elements (FRTE), rare-earth elements (REE), large-ion lithophile
116 elements (LILE), and high field strength elements (HFSE). Seventeen of these elements have not
117 been previously reported for plagioclase from 76535, and eleven have never been reported for
118 any phase of 76535.

119 The second objective of this study is to build on these methods and estimate the true Mg-
120 suite parental liquid by (1) utilizing the improved characterization of the REE concentrations
121 within sample 76535 obtained for this work and using improved partitioning behaviors calibrated
122 for lunar magmas, (2) verifying that the measured REE concentrations reflect magmatic
123 conditions, and (3) employing a parental liquid forward model which more accurately estimates
124 the Mg-suite parental liquid. The Earlier estimates of the REEs in the Mg-suite parental liquid
125 performed by Haskin et al. (1974), Papike (1996), and Shervais and McGee (1998) are shown in
126 figure 1. These estimates used experimentally determined partition coefficients to invert REE
127 data from major phases within 76535 and other Mg-suite norites and troctolites. We note that this
128 inversion method estimates the REE concentration of the liquid in equilibrium with the measured
129 phases and is highly sensitive to variations in REE concentration and partition coefficient. The
130 accuracy of the inversion also relies on the assumption that the measured REE concentrations
131 reflect magmatic conditions and are free from subsolidus alteration. Given the lengthy subsolidus
132 cooling history of 76535 (estimated cooling rate of 3.9 C/ Myr, Borg et al., 2017), there is a
133 possibility of readjustment of REE abundances due to subsolidus diffusion, which needed to be
134 accounted for. Furthermore, the estimated equilibrium liquids are likely more REE-enriched than
135 the true Mg-suite parental liquid, as the phases measured in those studies were likely not on the

136 liquidus of the true parental liquid but were likely in equilibrium with a residual liquid along the
 137 liquid line of descent which is comparatively more REE-enriched (Treiman, 1996).

138 The final objective of this work is to constrain the extent of ur-KREEP assimilation to the
 139 Mg-suite parental liquid. Using the estimated parental liquid REE concentrations, we can explore

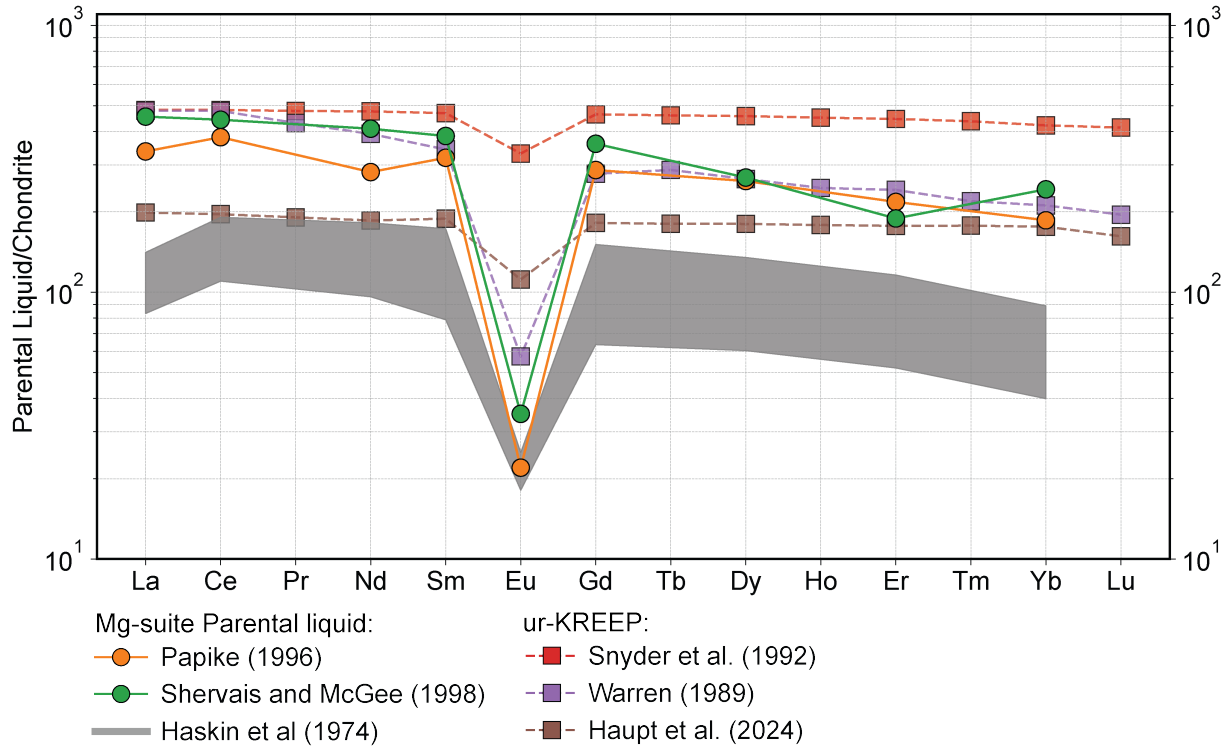

Figure 1. Mg-suite parental liquid REE concentrations estimated by inverting REE data from Mg-suite samples with mineral-melt partition coefficients. These estimations show a clear similarity with the plotted ur-KREEP compositions. However, the phases used in these inversions were likely not liquidus phases and, therefore, reflect the fractionated residual liquid in equilibrium with the measured phase instead of the true Mg-suite parental liquid. Haskin et al., 1974 data are from plagioclase from 76535-21,22, Papike, 1996 data are averages of Apollo 17 norites, Shervais and McGee (1998) data are averages of Mg-suite troctolites from Apollo 17 and 14.

140 its petrogenesis by trying to reproduce it through the mixing of possible Mg-suite primary
 141 parental liquid compositions with modeled ur-KREEP compositions. By constraining the extent
 142 of ur-KREEP assimilation, we can improve upon current models of Mg-suite formation, which is
 143 a key factor in the internal evolution of the Moon. Importantly, we also demonstrate through this
 144 study that geochemical characterization of only a few mineral grains can provide vital
 145 information about the petrogenesis of the sample. We therefore present an approach of
 146 maximizing scientific output from returned planetary samples in the future, including the
 147 Artemis missions.

148

149 **BACKGROUND - Petrographic and Geochemical Characterization of 76535**

150 Sample 76535 is a 155.5 g troctolite sample collected during a rake. The mineralogy and major
151 element chemistry of 76535 have been extensively described (Dymek et al., 1975; Gooley et al.,
152 1974; Haskin et al., 1974a, 1974b; Bogard et al., 1975; Nord et al., 1976). The mineralogical
153 composition corresponds to 58% plagioclase (An_{96.2}), 39% olivine (Fo_{87.3}), and 2%
154 orthopyroxene (Wo_{0.9}, En_{84.1}, Fs_{11.3}), with trace amounts of clinopyroxene, chromite spinel,
155 apatite, baddeleyite, merrillite, and Fe-Ni alloy. 76535 has a cumulate texture, with the majority
156 of accessory minerals found in mesostasis assemblages. Thermobarometric calculations for
157 76535 crystallization indicate a 0.2-0.3 GPa and 800-1000 °C cooling regime (Gooley et al.,
158 1974; McCallum and O'Brien, 1996; Schwartz and McCallum, 1999, 2001; White et al., 2020).
159 Borg et al. (2017) used a combination of multiple geochronometers, Sm-Nd, Ar-Ar, and Rb-Sr,
160 and assumed a linear cooling rate to calculate a solidus age of 4384 ± 24 Ma for 76535 and a
161 subsolidus cooling rate of 3.9 °C/Ma. These data are consistent with low-pressure granulite
162 facies metamorphism evidenced by grain annealing and numerous triple-grain junctions. The
163 possible effects of this metamorphism on the chemistry of 76535 will be discussed in greater
164 detail below.

165 The plagioclase separates from 76535-11 used in this study were previously analyzed for
166 isotopic and bulk chemistry. They were prepared and analyzed by Papanastassiou and
167 Wasserburg (1976) for Rb-Sr and analyzed by Borg et al. (2015, 2017) for Rb-Sr and Sm-Nd
168 systematics. A full description of the preparation of these grains can be found in their work.
169 Briefly, Papanastassiou and Wasserburg (1976) disaggregated the subsample, repeatedly crushed
170 it, and sorted it into mineral separates. During this process, cumulus plagioclase grains,
171 originally ~1 cm (Gooley et al., 1974), were crushed into smaller grains of various sizes. The
172 most important effect of this process on this work is the potential for the analyzed material to
173 contain either core or rim material or a mixture of both. A determination of the origin of the
174 analyzed grains is included later on.

175 176 **METHODS**

177 For this study, four plagioclase grain separates from 76535-11 were requisitioned from the
178 Astromaterials Allocation Review Board (AARB). These 1 mm diameter grains (denoted as P-1
179 to P-4) were mounted in indium and polished using diamond lapping film with 15 and 9 μm
180 grits, followed by powdered diamond abrasives with 3 and 1 μm grits. The chemistry of these
181 mounted grains was then analyzed through an Electron Probe Micro Analyzer (EPMA),
182 Secondary Ion Mass Spectrometry (SIMS), and Laser Ablation Inductively Coupled Mass

EMPA Analyses
 SIMS Analyses
 LA-ICP-MS Lines

Figure 2. Reflected light photographs of the plagioclase separates with the locations of the different analysis techniques indicated. Grains were polished between analyses to provide adequate surface space for subsequent analyses. Grains P-1 and P-4 show good cleavage into/out of the image plane. However, no systematic chemical variation was observed between P-1/P-4 and P-2/P-3. Letters indicate locations of EPMA (A-A', E-E', and H-H') and SIMS (B-B', C-C', D-D', F-F', G-G', H-H', I-I', and J-J') transects.

183 Spectrometry (LA-ICP-MS). Complete raw data files from these analyses are available in the
 184 supplementary information. Si, Al, Ca, Na, K, Mg, Mn, Fe, Cr, Ti, and Ba concentrations were
 185 measured on grains P-1, P-2, and P-4 using a Cameca SX100 EPMA at the University of Arizona
 186 Kuiper-Arizona Laboratory for Astromaterials Analysis under the following operating
 187 conditions: an accelerating voltage of 15 keV, a beam current of 10-20 nA, and a 5 μm beam
 188 diameter. This beam diameter was chosen to limit Na migration during analysis (Kuehn, 2016).
 189 The complete list of standards used is provided in the supplemental material., Count times were
 190 10 seconds for Na, Ba, and K and 20 seconds for all other elements. Peak and background counts
 191 for individual elements are included in the supplemental materials.

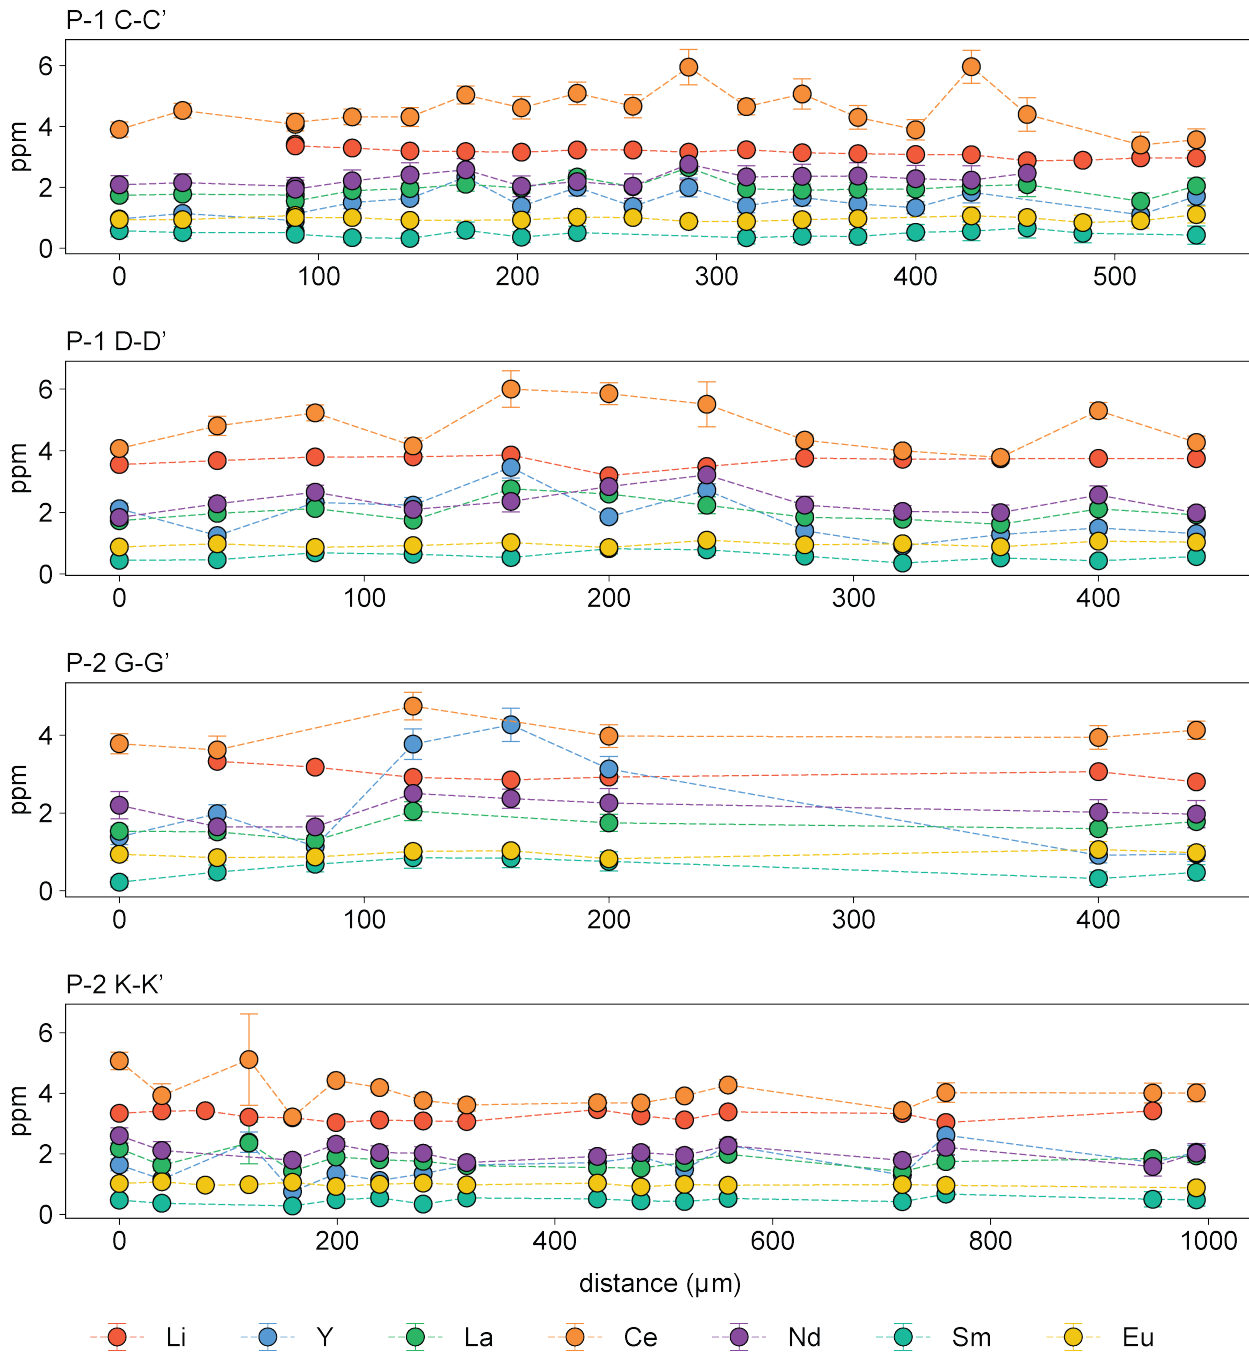

Figure 4. LREE concentrations measured in orthogonal SIMS analysis transects of grains P-1 (C-C', D-D') and P-2 (G-G', H-H'). The location of these transects is shown in figure 1 by black lines. Outliers have been removed based on the Z score and the homogeneity index (discussed further below). The analysis transect of P-4 is available in the supplemental material.

201 Twenty-nine trace and four minor element concentrations in all four grains were measured
 202 by LA-ICP-MS at the University of Arizona geosciences department. Measurements were
 203 performed using an Element™ Series high-resolution ICP-MS and an X-Series II multi-collector
 204 ICP-MS. Both ICP-MS instruments were coupled to an NWR femtosecond laser with a 100% He

Figure 5. Semi-log plot of REE concentrations of each grain measured on the Element™ high-resolution IC-PMS normalized to chondritic REE values from McDonough and Sun (1995) with 2 SD errors shown. These measurements from this study (P-1, P-2, P-3, and P-4) plot slightly below the solution-based results of Borg et al. (2017) and Haskin et al. (1974). The higher concentrations observed by Borg et al. (2017) and Haskin et al. (1974) may be due to impurities in the digested material., Such impurities may include REE-enriched mineral rims or REE-rich non-plagioclase phases. The positive Yb anomaly may also be due to low total counts and natural abundances of even-numbered Elements.

205 carrier gas. 4 separate ablations lasting 20 seconds each were conducted on each grain in a series
 206 of 300 μm line scans with a 50 μm diameter spot size. Three of the ablations were run at $2.8 \frac{\text{J}}{\text{m}^2}$,
 207 while the final ablation, which measured the REEs, was run at $7.7 \frac{\text{J}}{\text{m}^2}$. A repetition rate of 250 Hz
 208 was used for each analysis. Data reductions, including background subtraction, calibration
 209 surface creation, and drift corrections, were carried out in Iolite 4™ using the 3D trace element
 210 data reduction scheme (Paton et al., 2011; Paul et al., 2023). Trace element yields were
 211 normalized to NIST (SRM 616, 614, 612, and 610) and USGS glasses (BHVO, BCR)—a full
 212 table of analysis parameters is available in the supplemental materials.

213

214 RESULTS

215 Major and minor element analyses were completed on the plagioclase grain separates. Analytical
 216 results for major elements of grains P-1, P-2, and P-4, as measured by EMPA, are reported in
 217 table 1 and figure 3. The average An content of the three measured grains is 97.6 ± 6 , which is
 218 consistent with previous measurements of 76535 plagioclase (Haskin et al., 1974; Borg et al.,
 219 2017) and plagioclase within the wider Mg-suite (Shearer et al., 2015). Minor element
 220 measurements from EMPA and SIMS (table 1 and figure 4) are in good agreement.

Figure 6. Semi-log plot of REE concentrations of each grain measured on the X-Series II multi-collector ICP-MS normalized to chondritic REE values from McDonough and Sun (1995) with 2 SD errors shown. These measurements, like those made by the Element™ plot slightly below the solution-based results of Borg et al. (2017) and Haskin et al. (1974). Figure 7. Estimated diffusion profiles between plagioclase and olivine calculated at constant Nd diffusivity plotted at 5 Ma intervals. Diffusion profiles extend a maximum of 300 μm into the plagioclase grains. This diffusion profile calculated using the chosen Nd diffusivity of $1.12 \times 10^{-23} \text{ m}^2/\text{s}$, which corresponds to 900 °C and An₉₃, represents an upper bound on possible diffusive profiles. The SIMS analysis transects for P-1 (C-C' and D-D') are also plotted to show the inconsistency of the measured concentration topography with the predicted diffusion profiles.

221 The results of the SIMS transects are recorded in figure 4. Measurements for both groups
 222 of elements were normalized to the counts of Si, and a correction for BaO interference with Eu
 223 was applied (Hinton, 1990). Because the chemistry of the plagioclase crystals does not change
 224 (relative to the uncertainty of analysis) across the grain, we would label the crystals as
 225 homogeneous. Because the grains are not in situ, their rims cannot be identified with certainty.
 226 Nevertheless, the fact that all grains are compositionally consistent across their surfaces implies
 227 minimal zoning in the sample and supports the interpretation that the material measured for this
 228 work comes from grain cores. The quantification of this homogeneity in LREEs will be
 229 discussed later on.

230 The results of the LA-ICP-MS are shown in table 2. These analyses reveal enrichments in
 231 LREEs between 1- and 10-times chondritic values. HREEs are depleted by about 0.1 times
 232 relative to chondrites. The SIMS and LA-ICP-MS analyses deliver similar abundances for Ba,
 233 Sr, and Y. The increased counts on the LA-ICP-MS allow for better, higher precision
 234 measurements of HREEs, which range from ~3 to ~400 ppb. The positive Yb anomaly seen in P-

235 2, P-3, and P-4 may be an artifact of the low total counts for individual HREEs and the naturally
236 more abundant even-numbered elements. Notwithstanding, the La/Yb ratio of the samples ranges
237 from 10 to 30, consistent with previous measurements of 76535 plagioclase (Haskin et al., 1974;
238 Borg et al., 2017). The solution-based ICP-MS of 76535-11 by Borg et al., 2017 is also reported
239 in figures 5 and 6. The separation of the HREE data from Borg et al. (2017) and that of this study
240 may arise from impurities within the mineral separates and the mixture of grain cores and rims,
241 which may have different REE concentrations in the dissolved material for the solution-based
242 methods, highlighting the importance of in-situ characterization over bulk characterization in this
243 context.

244

245 **DISCUSSION**

246 Determining the petrogenesis of the Mg-suite requires an accurate characterization of its parental
247 liquid. Fixing the parental REE composition allows us to evaluate the hypotheses that ur-
248 KREEP material contributed to the petrogenesis of the Mg-suite. The inversion method
249 used by previous studies for estimating REEs in the Mg-suite parental liquid estimate
250 the concentrations of the residual liquid at the point on the liquid line of descent where
251 the analyzed material was on its liquidus. To accurately assess the potential for ur-KREEP
252 assimilation, the ‘true’ parental liquid of Mg-suite magmas is needed.

253 To this end, a Python-based forward model was created, which utilizes a modeled Mg-suite
254 liquid line of descent (LLD). The accuracy of this forward model relies on first determining that
255 the sample preserves its magmatic chemistry (Shervais and McGee, 1998). We present here two
256 lines of evidence that support the assumption that the REE measurements we performed are
257 representative of magmatic conditions. The first is the statistical quantification of the
258 homogeneity of these grains, as revealed by the SIMS analysis transects. The second is a
259 calculation of diffusive profiles within plagioclase, which explores possible subsolidus diffusion
260 of REEs.

261

262 **Grain Homogeneity**

263 A significant advantage of our microanalysis studies is the ability to detect intragrain
264 heterogeneity at a scale of a few tens of microns, which is not achievable with solution-based
265 analyses. Characterizing the homogeneity of REEs within 76535 plagioclase serves to increase
266 the confidence of our measured REE values as it provides a criterion to reject anomalous
267 measurements. Additionally, a homogeneous sample will be free from concentration gradients,
268 the products of slow crystallization or subsolidus diffusion. Both of these effects serve to
269 increase the confidence of our modeled parental liquid.

270 Quantifying a sample’s homogeneity requires distinguishing the effects of the measurement
271 uncertainty from true compositional variations within the material., Harries (2014) presents a
272 model to estimate the contribution of compositional heterogeneity S_h and measurement
273 uncertainty (S_{rms}) to the combined uncertainty budget (S_c) of geologic reference materials. This
274 model creates a statistically sound method for quantifying the homogeneity of the sample
275 through a homogeneity index (H) and F statistics. Equation 1 shows the relationship presented by
276 Harries (2014), where S_c

277

$$H = \frac{E(S_c)}{E(S_{meas})} \approx \frac{S_c}{S_{rms}} \quad (1)$$

Table 3. Homogeneity Indices

Errors on H values are minimum uncertainty of H calculated following methods in Harries (2014).

279 root mean square of the uncertainties of the mass fractions. A homogeneous material will,
280 therefore, return an H value of ~ 1 . The homogeneity index (H) is the square root of a variance
281 ratio, and it follows, therefore, that H^2 is a variance ratio that can be used to test the null
282 hypothesis shown in equation 2. In this hypothesis, $E(S_c)$ represents the expected variance of the
283 combined uncertainty, and

$$E(S_c^2) = E(S_{meas}^2) \quad (2)$$

285 $E(S_{meas})$ is the expected variance due to measurement uncertainty. Equation 3 outlines the
286 F-test used to calculate the probability of rejecting the null hypothesis. $F_{(\alpha, v_1, v_2)}$ is the critical F
287 value which incorporates the degrees of freedom of S_c and S_{rms} , $v_1 = N-1$ and $v_2 = \text{infinity}$
288 respectively. The

$$H^2 > F_{(\alpha, v_1, v_2)} \quad (3)$$

290 significance level alpha was set at 0.01, corresponding to the probability of falsely
291 rejecting the null hypothesis (considering a homogeneous material heterogeneous).

292 Failing to reject the null hypothesis in this test boosts our confidence in the spatial
293 homogeneity of the sample. This outcome also provides a basis for dismissing outlier values as
294 unrepresentative. The calculations of the homogeneity index and the subsequent F test using the
295 SIMS transect data are detailed in table 3. The analyzed grains contain no detectable
296 heterogeneity, with the majority of H values being < 1 . Additionally, we calculated a
297 homogeneity index for the combination of the three grains, which revealed measurable inter-
298 grain heterogeneity in lithium only. The observed high inter-grain (excluding Li) and intra-grain
299 homogeneity align with previous assessments of mineral chemistry in sample 76535 (Haskin et
300 al., 1974). In the absence of complete diffusive homogenization, this result suggests that the
301 measured REE concentrations accurately reflect the magmatic concentrations of the parental
302 liquid at the time of crystallization. In the following section, the potential for diffusive
303 homogenization is explored.

304

305 **Subsolidus Diffusion of Trace Elements**

306 The slow cooling and granoblastic texture of the original 76535 plagioclase necessitates
307 consideration of subsolidus diffusive processes to assess the suggestion that the measured trace
308 element concentrations reflect plagioclase-magma equilibrium conditions (Shervais and McGee,
309 1998; Warren et al., 1993). Given the nature of the plagioclase separates it is possible that the
310 material measured for this work, represents entirely grain core or rim material, or a mixture of
311 both. To this end, we employed a one-dimensional diffusion model that simulates the migration
312 of Nd from plagioclase into neighboring olivine. Our objective with this exercise is to define a
313 possible Nd diffusion profile within a hypothetical 76535 plagioclase and compare those
314 estimates to the topography of Nd concentrations in the SIMS analysis transects. The result of
315 this exercise will be determining whether the measured material is grain core material, and the
316 extent that that Nd has been affected by diffusion. Given their limited range of ionic radii, the
317 result of this exercise is expected to be applicable to all REEs, not just Nd. The model utilized a
318 one-dimensional, non-steady-state diffusion framework, treating the plagioclase and surrounding
319 olivine as discrete segments, with Dirichlet boundary conditions applied at both ends. Diffusion
320 was modeled using an analytical solution to Fick's Second Law (Mehrer, 2007) shown in
321 equation 4, where c_1 and c_2 denote the concentrations in plagioclase and olivine, respectively, D
322 represents the diffusivity of Nd in plagioclase, and t represents time in millions of years.

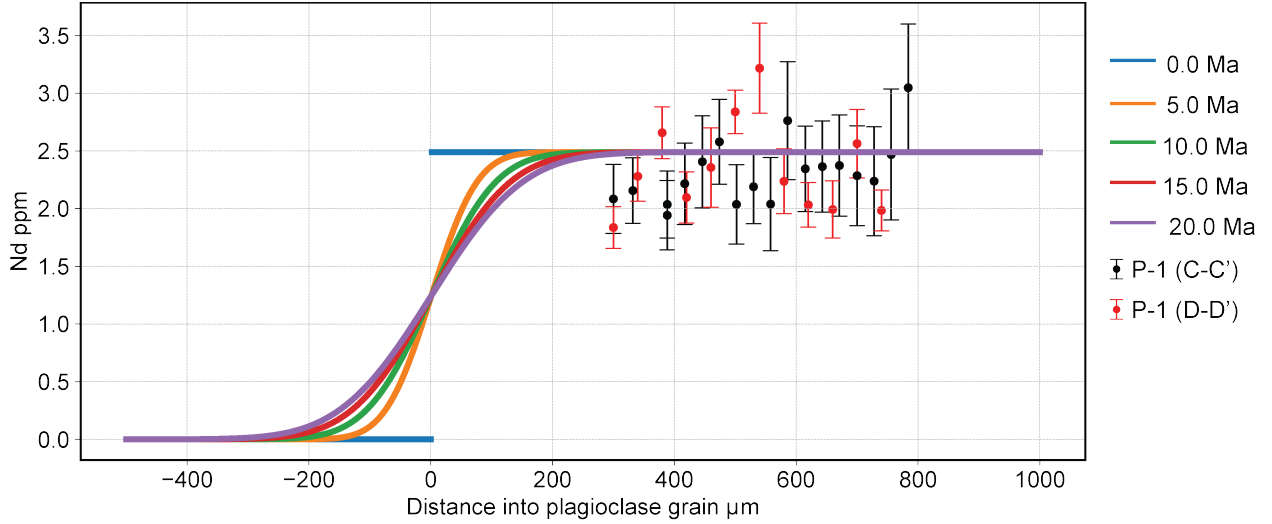

Figure 7. Estimated diffusion profiles between Plagioclase and olivine calculated at constant Nd diffusivity plotted at 5 Ma intervals. Diffusion profiles extend a maximum of 300 μm into the plagioclase grains. The chosen Nd diffusivity of $1.12 \times 10^{-23} \text{ m}^2/\text{s}$ corresponds to 900 $^\circ\text{C}$ and An93 represents an upper bound on possible diffusive profiles. The SIMS analysis transects for P-1 (C-C' and D-D') are also plotted to show the inconsistency of the concentration topography with the predicted diffusion profiles.

323

$$324 \quad c(x, t) = \frac{(c_2 - c_1)}{2} \left(1 + \operatorname{erf} \left(\frac{x}{2\sqrt{Dt}} \right) \right) \quad (4)$$

325 The initial Nd of plagioclase in the model was set at 2.615 ppm, the Nd measured in 76535-
 326 11 plagioclase by Borg et al., 2017 and the initial Nd in olivine was 0.125 ppm as measured in
 327 76535, 21-22 by Haskin et al., 1974. The Nd diffusivity used in this model was calculated for
 328 An93 at 900 $^\circ\text{C}$ using the Arrhenius relation outlined in equation 4 (Cherniak et al., 2003), where
 329 R represents the gas constant ($8.314 \times 10^{-3} \frac{\text{kJ}}{\text{mol}} \cdot \text{K}$) and T is the temperature in Kelvin.
 330 Diffusivity in plagioclase

$$331 \quad D = 5.9 \times 10^{-6} \exp \left(\frac{-398}{RT} \right) \quad (5)$$

332 is inversely. Correlated with both temperature and calcium content (Cherniak et al., 2003),
 333 therefore holding diffusivity constant at $1.12 \times 10^{-23} \frac{\text{m}^2}{\text{s}^2}$, the value corresponding to 900 $^\circ\text{C}$ for
 334 An 93, estimates an upper limit for potential diffusion in the An 97 plagioclase from 76535.
 335 Diffusion was modeled this way over 20 Ma, consistent with the subsolidus cooling rate of 3.9
 336 $\frac{^\circ\text{C}}{\text{Ma}}$ defined by Borg et al. (2017) from the solidus at approximately 900 $^\circ\text{C}$, as determined by
 337 RhyoliteMELTS (Gualda et al., 2012; Ghiorso et al., 1995; Asimow and Ghiorso, 1998), to the
 338 closure temperature of Nd in Plagioclase around 825 $^\circ\text{C}$, (Borg et al., 2017). The modeled
 339 diffusion profiles generated from this solution are presented in figure 7. The modeled diffusion
 340 profiles after 20 million years extend a maximum of 300 μm into the plagioclase grains, with
 341 pronounced diffusion occurring near the grain edges. This diffusion creates a profile that matches

342 Na α X-ray intensity maps of 76535-55 plagioclase (Nelson et al., 2021) and 14321 (Shervais
343 and McGee, 1998) and would be detectable with the analytical precision of the SIMS. The SIMS
344 analyses transects revealed no core-to-edge diffusive profiles or noticeable heterogeneity,
345 suggesting that the measured REE concentrations sample the core of original plagioclase grains
346 and represent magmatic conditions. The absence of observable diffusion profiles suggests that
347 the material sampled in this study originated from the core of cumulus plagioclase grains.
348 Therefore, we feel confident in the assumption that the measured concentrations of Nd and other
349 REEs are magmatic.

350

351 **Estimating Parental Melt Composition**

352 We estimated the unfractionated Mg-suite parental liquid using a Python-based forward model.
353 This model relies on a modeled LLD created using the thermodynamic code RhyoliteMELTS
354 1.0.2 (Gualda et al., 2012, Ghiorso et al., 1995; Asimow and Ghiorso, 1998). The LLD was
355 calculated using a potential Mg-suite parental liquid major element composition first proposed
356 by Longhi et al., 2010 and adapted by Prissel et al., 2016 as a starting liquid, which was then
357 fractionally crystallized from the liquidus at approximately 1544 °C to 900 °C. This major
358 element composition was selected because it has been shown to reproduce the mineralogy of the
359 Mg-suite troctolites (Prissel et al., 2016). RhyoliteMELTS-defined LLD provides the mass
360 fraction and composition of Minerals being fractionated from the starting liquid at each
361 temperature step. The pressure for these calculations was set at 0.26 GPa, consistent with
362 available Thermobarometric data (Gooley et al., 1974; McCallum and O'Brien, 1996; Schwartz
363 and McCallum, 1999, 2001; White et al., 2020). The forward model then ascribes an initial guess
364 for each REE to the starting liquid, which is then fractionated into each phase as it forms based
365 on the calculated mineral-melt partition coefficient for spinel, olivine, plagioclase,
366 orthopyroxene, and clinopyroxene. The methods for calculating these partition coefficients are
367 detailed in the following sections. The forward model, therefore, produces a set of fractionated
368 minerals with their equilibrium REE content at each temperature step along the LLD. The initial
369 guess of each REE in the parental liquid was then varied until a plagioclase with REE
370 concentrations matching those measured in the 76535 plagioclase was fractionated within a
371 target temperature window (1244 °C -1256 °C). The target temperature window was determined
372 as the range of temperature where the fractionated mineral most closely matched the modal
373 mineralogy of 76535. The input files used in calculating the LLD RhyoliteMELTS input and
374 output files are included in the supplemental materials available on ReData (See Appendix B).
375 The method for calculating the unfractionated parental liquid is outlined in figure 8 and the
376 results of this forward model are shown in figure 9.

377 This exercise reveals a parental liquid with a strong resemblance to calculated ur-KREEP
378 compositions, being enriched to 100s of times chondritic values with a decreasing trend towards
379 HREEs. Additionally, inversion was used to estimate the fractionated parental liquid when
380 plagioclase was on the liquidus using the data from this study along with data from Borg et al.
381 (2017), Haskin et al. (2017), and Shervais and McGee (1998). The plagioclase-melt partition
382 coefficients for these inversions were calculated at 1271 °C; the temperature that plagioclase
383 appears on the liquidus, as defined by RhyoliteMELTS. These fractionated liquids, plotted in
384 figure 9, show additional enrichments in REEs. Finally, we inverted the 78235 norite plagioclase
385 compositions from Papike (1996) which is more enriched still. These estimates and the
386 unfractionated parental liquid may represent various points along the crystallization of a single

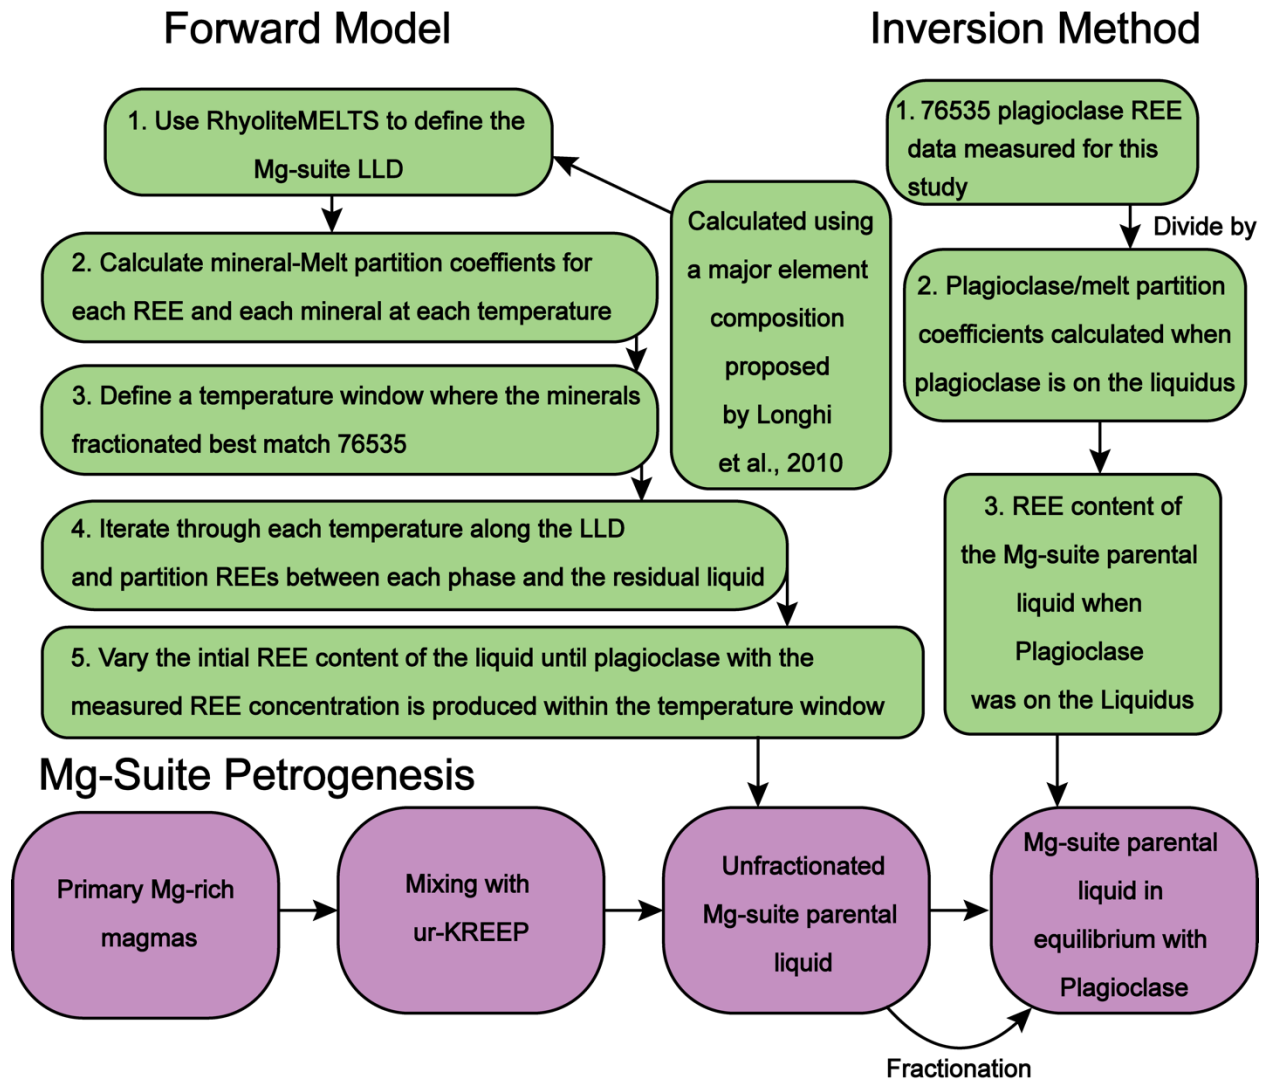

Figure 8. Flow chart outlining the process of calculating the unfractionated parental liquid through the forward model and inversion. Green squares represent the processes involved in estimating the parental liquid and the purple squares shows where in the petrogenesis of the Mg-suite these estimated liquids fit.

387 magma. Now that we are confident in the accuracy of our estimated parental liquid composition,
 388 we explore the petrogenesis of the Mg-suite and assess the extent of ur-KREEP assimilation.
 389

390 **Mineral-melt Partition coefficients**

391 Partition coefficients between the phases of the RhyoliteMELTS-defined LLD and the residual
 392 liquid are required to recreate the parental liquid. These coefficients, representing the expected
 393 concentration ratio of an element between two phases, can be sensitive to various factors and
 394 have been the topic of extensive experimental investigations. Previous estimates of the Mg-suite
 395 parental liquid used a range of published partition coefficients to invert measured sample REE
 396 data (Haskin et al., 1974; Papike 1996; Shervais and McGee, 1998; shown in figure 1) The

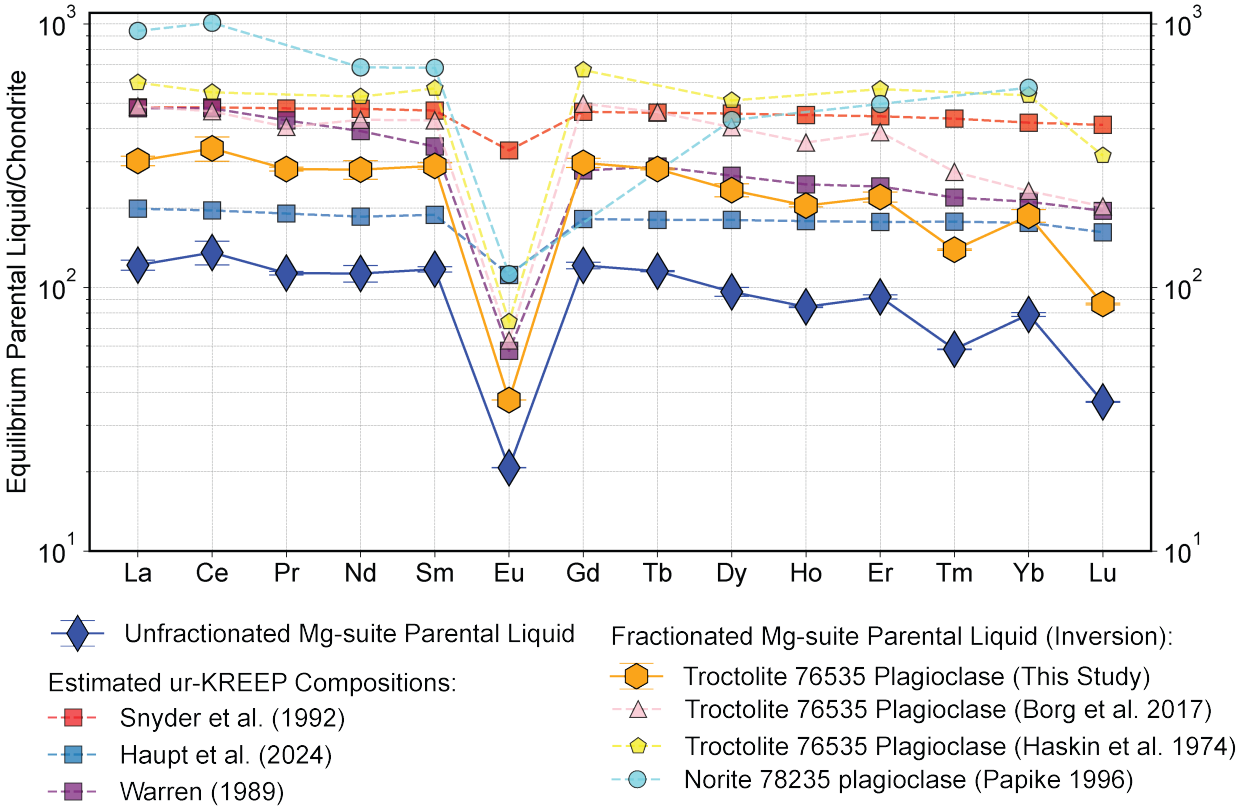

Figure 9. Semi-log plot of the estimated parental liquids normalized to chondritic REE values from McDonough and Sun (1995). Errors on parental liquids from this study are two standard error, calculated through a Monte Carlo simulation following the methods of Anderson, 1976. For most points, the errors are too small to see at this scale. Ur-KREEP compositions are plotted as squares to distinguish them from estimated parental liquids.

397 parental liquid in both the inversion methods and the forward model presented in the previous
 398 section are highly sensitive to the partition coefficient values, necessitating careful consideration
 399 of how the values are determined.

400 The partition coefficients for olivine, orthopyroxene, clinopyroxene, and plagioclase were
 401 calculated using the lattice strain model proposed by Blundy and Wood (2003) shown in
 402 equation r. In this

$$403 \quad D_{\text{REE}}^{\text{min-melt}} = D_0 \exp \left[\frac{-4\pi EN_A}{RT} \left(\frac{r_0}{2} (r_0 - r_j)^2 - \frac{1}{3} (r_0 - r_j)^3 \right) \right] \quad (6)$$

404 model, D_0 represents the strain-free partition coefficient, r_0 , the strain-free lattice site ionic
 405 radius, and E_0 , the effective Young's modulus of the crystal lattice. Parametrization of these
 406 variables for olivine, orthopyroxene, and clinopyroxene was calculated through regression of
 407 existing experimental data by Sun et al. (2014). The pressure for the partition coefficient
 408 calculations was likewise set at 0.26 GPa, consistent with available Thermobarometric data
 409 (Gooley et al., 1974; McCallum and O'Brien, 1996; Schwartz and McCallum, 1999, 2001; White
 410 et al., 2020). A similar parametrization for plagioclase was performed by Sun et al. (2017),
 411 which incorporates experimental data produced by Sun et al., using lunar magma compositions.
 412 These parameterizations have been shown to fit the available experimental data at a range of

Figure 10. Semi-log plot showing the mixing exercise between the 15426 green glass (Borg et al., 2019) and the ur-KREEP concentration modeled by Warren et al., 1989 in comparison to the estimated Mg-suite parental liquid, both normalized to chondritic REE values from McDonough and Sun (1995). In this scenario, the ur-KREEP concentrations are more enriched in LREEs, similarly to the estimated parental liquid, negating the need for additional alteration of REEs with the parental liquid.

413 pressure, temperature, and liquid composition. No parametrization currently exists for spinel
 414 REE partitioning, so experimental values from (Irving, 1978) were used. Although the spinel
 415 partition coefficients are not as well constrained compared to the other phases, their effect on the
 416 estimated parental liquid is minimal due to the small mass fraction of spinel. These improved
 417 partitioning values, along with the high pristinity of 76535, the high homogeneity of the sample,
 418 and the high quality of our measurements, lend themselves to the estimation of a high-fidelity
 419 parental liquid composition.

420

421 Mg-suite Petrogenesis

422 Considering the high homogeneity and limited diffusion of REEs within 76535 plagioclase, and
 423 the strong KREEP signature of the estimated parental liquid, we suggest that a significant ur-
 424 KREEP contribution to the Mg-suite primary parental liquid is expected. This evidence, in
 425 combination with the previously presented chronological data leads us to propose the following
 426 model for Mg-suite formation: (1) FAN crystallization and ur-KREEP segregation at 4359 ± 9
 427 ± 9 Ma (Borg et al., 2017) and 4368 ± 29 Ma (Gaffney and Borg, 2014; Snape et al., 2016;

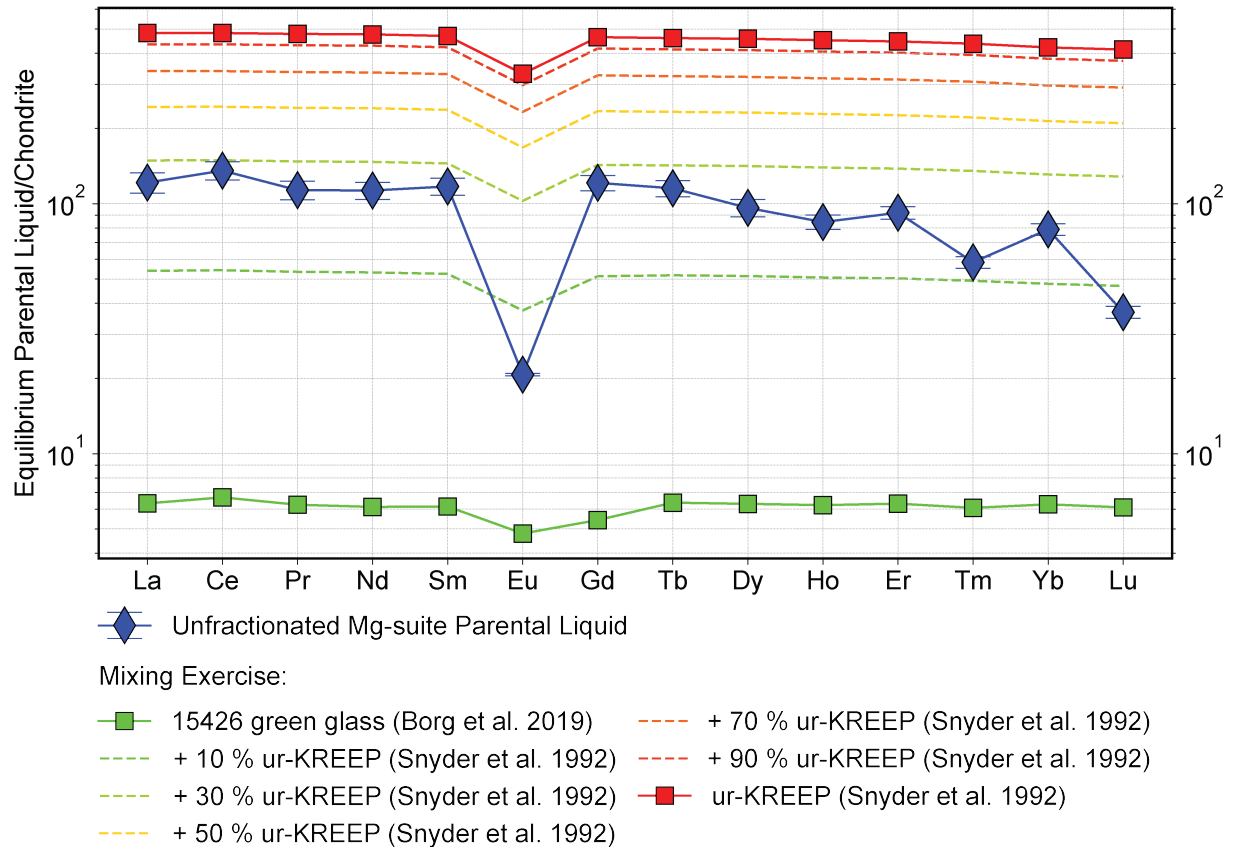

Figure 11. Semi-log plot showing the mixing exercise between the 15426 green glass (Borg et al., 2019) and the ur-KREEP concentration modeled by Snyder et al., 1992 in comparison to the estimated Mg-suite parental liquid both normalized to chondritic REE values from McDonough and Sun (1995). The HREE depletion in the parental liquid, cannot be explained by this mixing exercise alone and may require the fractionation of an HREE-rich phase which is explored in Figure 12.

428 and Maurice et al., 2020) respectively, (2) formation of the primary Mg-suite melt through
 429 decompression of rising magma ocean cumulates at 4345 ± 10 Ma (Borg et al., 2020),
 430 (3) assimilation of ur-KREEP material by the primary Mg-suite melt, leading to REE
 431 enrichment and formation of unfractionated parental liquid of Mg-suite; (4)
 432 fractionation of the parental liquid, and emplacement into the lunar crust. This
 433 petrogenetic model explains Cr-spinel bearing troctolites, whereas pink spinel troctolites
 434 or anorthosites require additional steps i.e. reaction of the parental liquid with crustal wall
 435 rock (Prissel et al., 2016 and Sheikh et al., 2024). The final objective of this work is to
 436 constrain the extent to which ur-KREEP material contributed to the Mg-suite primary parental
 437 liquid.

438 To this end, mixing exercises were conducted between different estimated ur-KREEP
 439 compositions (Haupt et al., 2024; Warren et al., 1989, and Snyder et al., 1992) and a potential
 440 primary Mg suite liquid. The REE compositions for potential Mg-suite primary parental melt
 441 were taken from 15426 green glass beads (Borg et al., 2019), which are believed to be among the

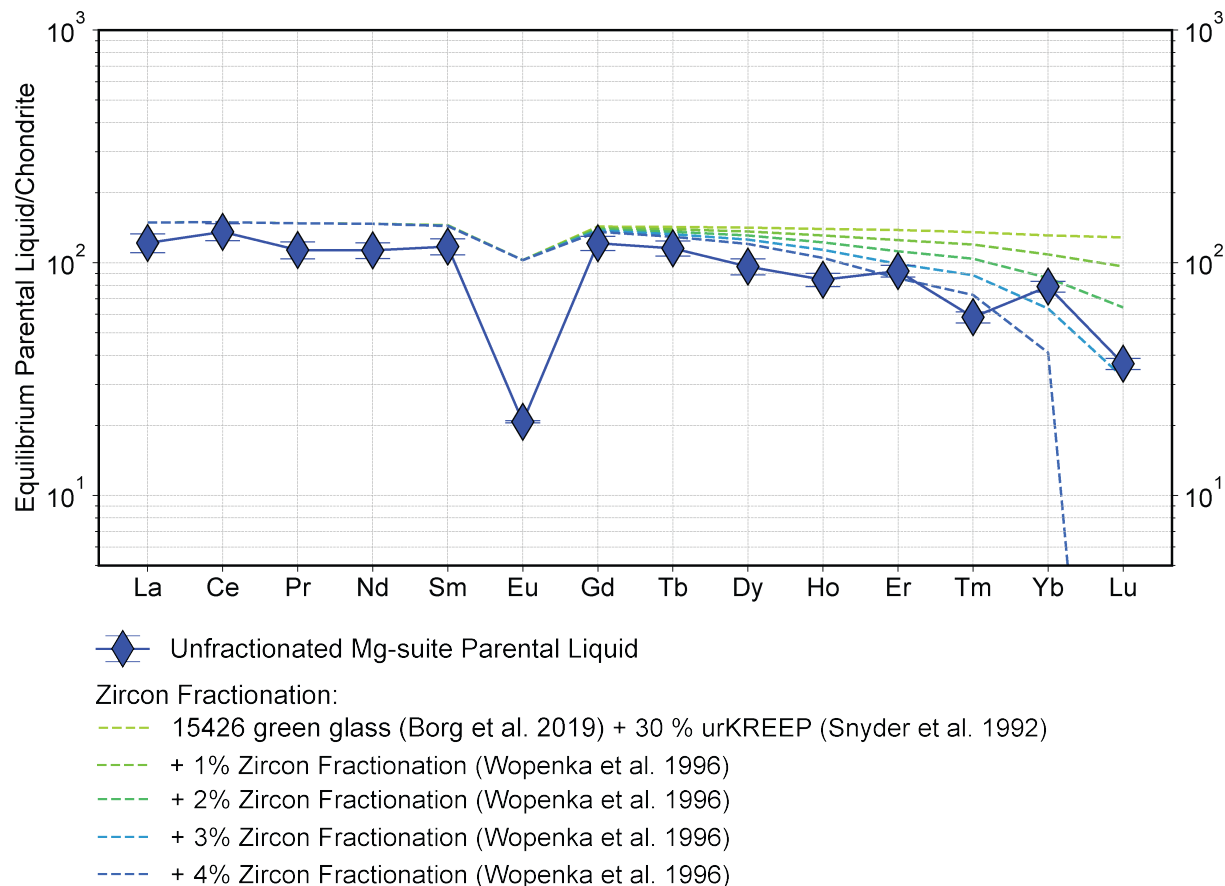

Figure 12. Semi-log plot simulating the fractionation of a lunar zircon Composition (Whitehouse and Nemchin, 2009) from a mixture of the 15426 green glass (Borg et al., 2019) and the ur-KREEP concentration modeled by Snyder et al., 1992 compared to the estimated Mg-suite parental liquid normalized to chondritic REE values from McDonough and Sun (1995). In this exercise, zircon represents a range of possible HREE-rich phases identified in 76535 and other Mg-suite samples, which include baddeleyite, merrillite, and zircons.

442 most primitive lunar volcanic rocks sampled thus far (Tatsumoto et al., 1987). These mixing
 443 exercises suggest that reproducing the estimated parental melt requires a 30-50% ur-KREEP
 444 contribution. The results of mixing ur-KREEP compositions from Warren (1989) and Snyder et
 445 al. (1992) are shown in figures 9 and 10, while the remaining mixing combinations are reported
 446 in the supplemental material.,

447 Some of the estimated ur-KREEP compositions contain flat REE trends (Snyder et al.,
 448 1992 and Haupt et al., 2024), which, in combination with the flat green glass trends (excluding
 449 Eu) (figures 10 and 11), cannot fully explain the REE composition of the estimated Mg-suite
 450 parental liquid. Thus, a two-stage model for Mg-suite petrogenesis may be necessary. This model
 451 would contain, first, a mafic primary melt that assimilates ur-KREEP material, and second, the
 452 fractionation of HREE-rich phases. This HREE depletion through fractionation was explored in a
 453 second mixing exercise. Figure 12 shows the results of zircon fractionation from a mixture of

Figure 13. Cartoon which demonstrates the outlined model for Mg-suite petrogenesis. In the first section, rising mafic cumulates are partially melted and come into contact with ur-KREEP in the upper mantle. These lithologies then mix in the second section, enriching the REE concentrations of the newly formed Mg-suite parental liquid. After this point the Mg-suite parental liquid continues to crystallize, further enriching the residual liquid to the REE concentrations which are estimated by the inversions of individual phases.

454 30% ur-KREEP (Snyder et al., 1992) and 70% 15426 green glass beads (Borg et al., 2019). In
 455 this exercise, a zircon REE concentration from Whitehouse and Nemchin (2009) is used as a
 456 stand-in for possible HREE-rich phases in Mg-suite samples (baddeleyite, merrillite, and
 457 zircons). The result of this exercise is that the HREE depletion in the parental liquid can be
 458 explained by 3-4% zircon fractionation, implying that a minor amount of HREE phase needs to
 459 be fractionated to explain the REE composition of the parental liquid. (see figure 12). Although
 460 not a major phase within Mg-suite samples, zircons and baddeleyite have been identified within
 461 Mg-suite troctolites, norites, and breccias. The ages of these zircons within Apollo and meteoritic
 462 Mg-suite samples are 4.332 ± 18 Ga and 4.354 ± 76 Ga, respectively (Zhang et al., 2021; Zhang
 463 et al., 2023). These ages coincide with the proposed pulse of Mg-suite magmatism at 4.4~4.3 Ga
 464 and a peak in zircon formation on the Moon at 4.33 Ga (Barboni et al., 2024), alluding to the
 465 possibility that the zircon formation and Mg-suite may be petrogenetically related such as a
 466 process proposed in this study. However, understanding the effects that ur-KREEP
 467 assimilation has on the major element chemistry and the phase equilibria (phase
 468 compositions and proportions) within the Mg-suite is beyond the scope of the present
 469 study and would require dedicated investigation in the future.

470

471 CONCLUSIONS

472 We measured major elements and thirty-three trace elements in plagioclase grain separates from
 473 troctolite 76535. The REE contents of these grains are consistent with known Mg-suite trends,
 474 namely, highly calcic plagioclase with enrichment in LREEs. The results of the microanalyses

475 also provide evidence for the preservation of the magmatic concentrations within these grains.
476 The samples exhibit high inter and intra-grain homogeneity and are likely sourced from the cores
477 of cumulus plagioclase grains, given the lack of the predicted diffusion profiles. Using these
478 measurements, we estimated the unfractionated Mg-suite parental liquid using a python-based
479 forward model and a RhyoliteMELTS-defined LLD.

480 The estimated parental liquid contains enrichments of LREEs ~100 times chondrite, which
481 decreases towards the HREEs being enriched only to ~ 10 times chondrite. Inversions of REE
482 data from 76535 and other Mg-suite samples predict more enriched liquids, which may represent
483 the continued fractionation of the Mg-suite parental liquid.

484 This study constrains the formation and crystallization of 76535 from the Mg-suite parental
485 melt and establishes limits for the ur-KREEP contribution to the primary Mg-suite melt. Mixing
486 and fractionation exercises indicate that the estimated Mg-suite parental liquid could be
487 explained by the assimilation of 30-40% ur-KREEP material if the primary liquid is highly REE-
488 depleted. Additionally, the fractionation of 4% zircon by weight may be necessary to account for
489 the observed HREE depletion in the estimated parental melt.

490 This study demonstrates that the geochemical characterization of only a few mineral grains
491 can provide key information about the petrogenesis of a lunar sample. We therefore present an
492 approach of maximizing scientific output from returned planetary samples in the future,
493 including the Artemis missions.

494

495 **ACKNOWLEDGEMENTS**

496 We are grateful to the AARB for loaning these samples to us and Ryan Ziegler (JSC, Houston)
497 for assisting us in the sample request process. We acknowledge the NASA Cosmochemistry,
498 Emerging Worlds, and Planetary Major Equipment Programs and the NSF Major Research
499 Instrumentation Program for funding of the instrumentation in the Kuiper Materials Imaging and
500 Characterization Facility at the University of Arizona. SIMS analysis at Arizona State University
501 was supported by NSF EAR 1819550. LA-ICP-MS analyses were performed with support from
502 the Lowell IMR Mineral Characterization Facility. We would like to thank Katherine Kelley
503 (University of Rhode Island) and Esteban Gazel (Cornell University) for their advice on
504 the laser ablation analyses, and Chip Shearer (University of New Mexico), Chenguang
505 Sun (Brown University), and Arkadeep Roy (University of Arizona) for helpful insights into
506 this work. IS acknowledges graduate funding from the University of Arizona Galileo Circle; The
507 Community Foundation for Southern AZ; and the Spencer R Titley Grad Fellowship and AM
508 acknowledges NASA grant 80NSSC24K0543 and start-up funds from the Eminent Scholars
509 Program managed by the Office of the Provost and the University of Arizona Foundation. We
510 also thank Karla Tellez for assisting with organizing the supplemental materials.

511

512 **Appendix A. Forward model parameters**

513 The basis for the forward model is a fractional crystallization sequence calculated in
514 AlphaMELTS. The input for this fractional crystallization sequence is included in the
515 supplementary materials and outlines the content of the major oxides, the fO_2 buffer, the initial
516 and final temperatures and pressures, and the type of fractionation. The file containing the major
517 element oxide mass fractions, which was input into RhyoliteMELTS, and the various output files
518 are available in the supplemental materials. These oxide concentrations were taken from Prissel
519 et al. (2016), who adapted the Mg-suite parental melt composition from Longhi et al. (2010),

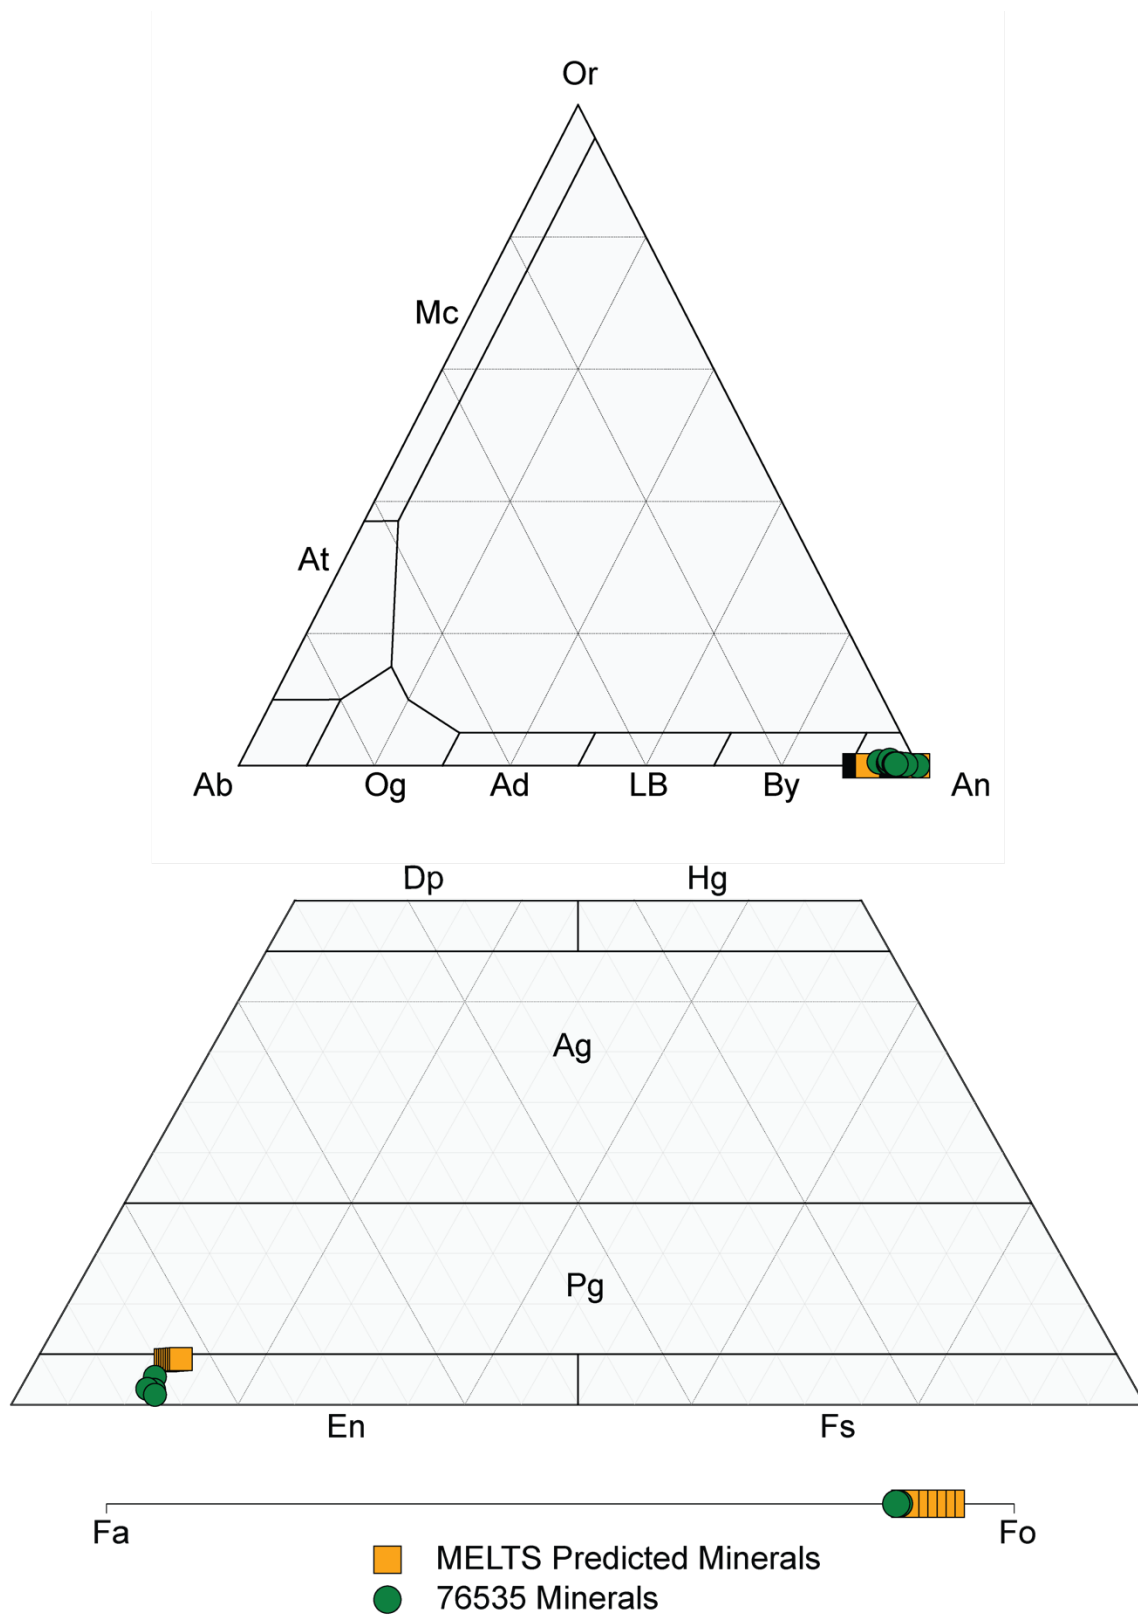

Figure 14. phase diagrams comparing major compositions of 76535 minerals to mineral compositions modeled by RhyoliteMELTS (Gualda et al., 2012; Ghiorso et al., 1995; Asimow and Ghiorso, 1998). The modeled minerals show a limited compositional range and therefore are a close match to 76535 minerals throughout the LLD.

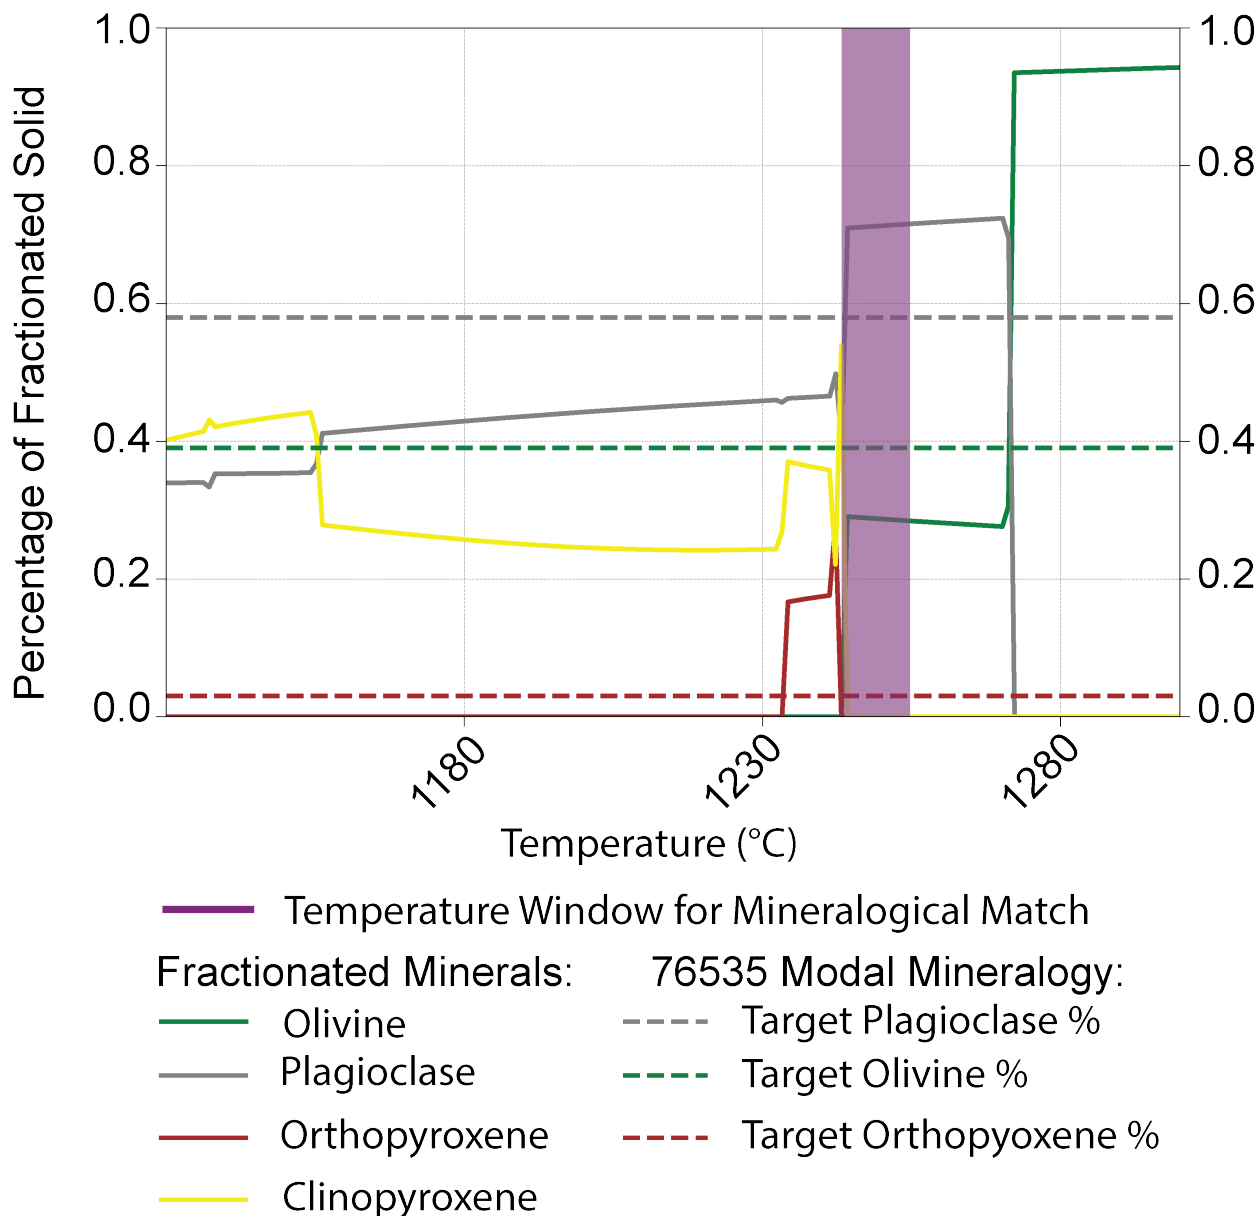

Figure 15. Mineralogy of fractionated minerals at each temperature of RhyoliteMELTS (Gualda et al., 2012; Ghiorso et al., 1995; Asimow and Ghiorso, 1998) fractional crystallization sequence. The Purple bar represents the range of temperatures in which the fractionated minerals most closely match the minerals of 76535 which was used in the forward model.

521 which represents a likely composition of the Mg-suite parental liquid. Due to the limitations of

522 the RhyoliteMELTS 1.0.2 software, Mn and K were excluded from the parental liquid. The fO_2
523 buffer was set at IW consistent with the lunar upper mantle (Herd, 2008; Wadhwa, 2008). The
524 initial temperature was set at 1500 °C, and the final temperature was set at 900 °C. The
525 temperature was set to 0.26 GPa, corresponding to multiple geobarometry calculations for 76535
526 (Gooley et al., 1974; McCallum and O'Brien, 1996; Schwartz and McCallum, 1999, 2001; White
527 et al., 2020). The outputs from the crystallization sequence are available in the supplementary
528 material., Figure 13 shows the mineralogy of the major phases (Plagioclase, Olivine, and
529 Orthopyroxene) as predicted by RhyoliteMELTS in comparison to the composition of 76535
530 minerals.

531
