19 **Abstract**

20 Abrupt changes in the Atlantic Meridional Overturning Circulation (AMOC)  
21 occurred in the past during Dansgaard-Oeschger and Heinrich events [1, 2], and  
22 an AMOC weakening, or possibly even collapse, is projected for the future [3]. The  
23 AMOC-driven glacial millennial-scale climate variability is associated with large  
24 changes in climate mainly over the North Atlantic region [4, 5], but extending also  
25 to the Southern Ocean, where they are particularly pronounced during Stadials  
26 featuring Heinrich events [6]. Here we use an Earth system model to show that the  
27 qualitative differences between Heinrich Stadials and non-Heinrich Stadials seen  
28 in many proxy records can be explained by a sudden start of convection in the  
29 Southern Ocean triggered by a collapse of the AMOC induced by large iceberg  
30 discharge in the North Atlantic during Heinrich events. The sudden convection  
31 onset results in rapid warming and sea ice retreat in the Southern Ocean and  
32 the resulting ventilation of the deep ocean explains the rapid CO<sub>2</sub> increase of

33 ~15 ppm on centennial time scales during some Heinrich Stadials seen in ice core  
34 records [7, 8]. We propose a general mechanism by which a stop of convection in  
35 the North Atlantic triggers convection in the Southern Ocean, in what we call a  
36 bipolar convection seesaw, which could also operate following a potential future  
37 AMOC collapse.

## 40 1 Introduction

41 There is widespread evidence of pronounced AMOC variability during glacial times  
42 associated with Dansgaard-Oeschger (DO) and Heinrich (H) events [1, 2, 9–11]. It  
43 is now widely accepted that DO events [12] can occur as part of internal variabil-  
44 ity of the ocean–sea ice–atmosphere system [13] involving spontaneous transitions  
45 between weak and strong AMOC modes under certain boundary conditions [14–16],  
46 implying alternating cold (Stadial) and warm (Interstadial) conditions in the North  
47 Atlantic. Additionally, large discharges of icebergs in the North Atlantic, so-called  
48 Heinrich events, originating from instabilities of the Laurentide ice sheet [17–19],  
49 occurred repeatedly during glacial times [20–22] and forced a weakening or collapse of  
50 the AMOC [11, 23] through the input of large amounts of freshwater into the North  
51 Atlantic [24]. Cold stadials containing Heinrich events are referred to as Heinrich  
52 Stadials (HSs).

53 While DO events have a large effect on climate over Greenland [4] and generally  
54 at high northern latitudes in the North Atlantic [25], some H events also have a large  
55 impact on climate at high latitudes in the Southern Hemisphere [6]. In particular, it  
56 has been noted that HSs and non-Heinrich Stadials (nHS), which are almost indis-  
57 tinguishable in Greenland ice core records, have a very distinct imprint on Antarctic  
58 climate and atmospheric greenhouse gases. Several proxy records hint at qualitative  
59 differences between HSs and nHSs that can not simply be explained by the different  
60 amplitude of AMOC perturbations: (i) a large and abrupt CO<sub>2</sub> increase by ~10-15  
61 ppm on centennial time scales during HSs as opposed to a steady decrease of CO<sub>2</sub>  
62 during nHSs [7, 8, 26, 27], (ii) a large and abrupt warming of 2-3°C over Antarctica  
63 during HSs [6, 28] and (iii) a sudden jump in atmospheric methane concentration dur-  
64 ing HSs [29]. Various proxies point to a crucial role played by the Southern Ocean  
65 (SO) to explain the peculiar dynamics during HSs, in particular through an increased  
66 ventilation of the SO [30–34], which is reflected also in the North Atlantic [35]. Sev-  
67 eral studies have invoked shifts in latitude or changes in intensity of the Southern  
68 Hemisphere westerly winds to explain the observed increase in ventilation of the water  
69 masses in the SO [8, 36–38], while some suggested enhanced convection and deep water  
70 formation to be the cause [33, 34, 39, 40], or a combination of the two processes [41].

71 However, modelling studies so far have failed to realistically reproduce the timing  
72 and amplitude of Antarctic temperature and atmospheric CO<sub>2</sub> variations during HSs  
73 or more generally in response to freshwater hosing in the North Atlantic designed

74 to mimic iceberg discharge associated with H events [42–50], except for simulations  
75 where convection in the SO was enforced to occur by applying an artificial negative  
76 freshwater flux at the surface in the SO [39]. Therefore, a mechanistic understanding  
77 of the relation between Northern Hemisphere (NH) and Southern Hemisphere (SH)  
78 climate response to AMOC variations remains elusive. Here we use a fast Earth system  
79 model with fully interactive carbon cycle to investigate the Earth system evolution  
80 during DO and H events and show that deep convection is triggered in the SO as  
81 a response to AMOC collapse following H events, explaining the observed large and  
82 abrupt Antarctic warming and atmospheric CO<sub>2</sub> increase.

## 83 **2 Simulated millennial-scale climate variability**

84 We use a fast Earth system model [52, 53] to simulate millennial-scale glacial climate  
85 variability (Methods). The model simulates spontaneous DO events under typical mid-  
86 glacial conditions [16], with jumps between Stadials and Interstadials being associated  
87 with transitions between two different AMOC states [16]. We additionally mimic the  
88 effect of a H event iceberg discharge through a prescribed plausible input of freshwater  
89 flux into the North Atlantic (Methods) and investigate the Earth system response to  
90 combined DO and H events in the model. We run a model simulation with interactive  
91 atmospheric CO<sub>2</sub> covering several DO cycles and a H event, with boundary conditions  
92 representative for MIS3, including mid-glacial ice sheets, an initial CO<sub>2</sub> of 205 ppm,  
93 a CH<sub>4</sub> concentration of 450 ppb, a N<sub>2</sub>O concentration of 240 ppb and present-day  
94 orbital configuration (Methods).

95 Our modelling results can be compared to different proxy records for MIS3. The  
96 time period around Heinrich Stadial 4 (HS4) has been particularly extensively studied  
97 in this respect, with many different high-resolution proxy records available for this  
98 period of time. We therefore use it here as a prototype of a succession of DO events  
99 and a pronounced HS to compare to our model simulation (Fig. 1).

100 In terms of temperature the model captures the shape of the response over Green-  
101 land, reflecting mainly DO variability associated with transitions in the AMOC state  
102 (Fig. 1a,g), even though the amplitude of the temperature change is underestimated in  
103 the model [16]. Moving south, the model reproduces very well the sea surface temper-  
104 ature response at the Iberian margin, with the cooling during the HS being as much  
105 as three times larger than during nHSs ( $\sim 5^\circ\text{C}$  compared to  $\sim 1.5^\circ\text{C}$ ) (Fig. 1b,h). Over  
106 Antarctica, temperatures increase rapidly during the middle of the HS, by  $\sim 3\text{--}4^\circ\text{C}$   
107 in the model and by  $\sim 2\text{--}3^\circ\text{C}$  in proxy data, while during nHSs the temperature increase  
108 is about a factor 3–5 smaller and happens more gradually during the entire duration  
109 of the Stadial (Fig. 1c,i).

110 The simulated CO<sub>2</sub> response to DO variability is generally within  $\sim 5$  ppm, in  
111 agreement with observations (Fig. 1d,j) and previous modelling results [49]. However,  
112 correspondingly to the abrupt warming over Antarctica during the HS, the model  
113 simulates a rapid increase in atmospheric CO<sub>2</sub> by  $\sim 15$  ppm (Fig. 1d,j). This is in good  
114 agreement with high-resolution CO<sub>2</sub> ice core record [7, 8], although it seems that the  
115 increase recorded in the ice core during HS4 was even more rapid than in the model  
116 (Fig. 1d,j). However, ice core data also indicate that the CO<sub>2</sub> increase was more gradual

117 during other HSs [8]. The  $\text{CO}_2$  response is partly dampened by the land carbon cycle  
118 absorbing part of the  $\text{CO}_2$  released by the ocean, and would be markedly larger in the  
119 absence of the land response (dashed line in Fig. 1j). The land absorbs carbon through  
120 a general increase in primary production due to the  $\text{CO}_2$  fertilisation effect induced  
121 by the increasing atmospheric  $\text{CO}_2$  concentration (Fig. A1f). The increase in  $\text{CO}_2$  is  
122 accompanied by a  $\sim 0.2$  permil decrease in  $\delta^{13}\text{C} - \text{CO}_2$ , matching ice core data [51]  
123 (Fig. 1e,k).

124 The model also qualitatively reproduces the response of atmospheric  $\text{CH}_4$  concentra-  
125 tion to DO and H variability (Fig. 1f,l), particularly if the  $\text{CO}_2$  fertilisation effect  
126 on primary production is disabled (dotted line in Fig. 1l).

127 Overall, the model reproduces the main features of climate and carbon cycle vari-  
128 ability associated with DO and H events, in particular the qualitative differences  
129 between HSs and nHSs.

### 130 **3 Southern Ocean convection during Heinrich** 131 **Stadials**

132 The simulated millennial-scale climate variability presented above is tightly linked to  
133 AMOC variations (Fig. 2a). The Atlantic ocean circulation is fundamentally different  
134 during HSs compared to nHSs. The latter are characterized by a substantially weaker  
135 AMOC compared to Interstadials (Fig. 2g,h), but with convection still active at sev-  
136 eral locations in the North Atlantic (Fig. 2d,e), while the large and abrupt freshwater  
137 input, which mimics iceberg discharge into the North Atlantic associated with the H  
138 event, leads to a rapid stop of convection and eventual shutdown of the AMOC in  
139 the model (Fig. 2f,i). Initially, the H event leads to a widespread cooling in the North  
140 Atlantic region and only limited localized warming in the South Atlantic (Fig. 3b).  
141 However, around 1000 years after the AMOC collapse, widespread convection is sud-  
142 denly triggered in the SO around Antarctica (Fig. 2b, 2f), following a more gradual  
143 convection onset in the Ross Sea (Fig. A2). The abrupt onset of convection has a pro-  
144 nounced impact on climate at high southern latitudes (Fig. 3c), resulting in a large  
145 initial warming due to heat released from the deep ocean and consequent large retreat  
146 of sea ice (Fig. 2c). The enhanced deep convection in the SO also leads to a strength-  
147 ening of Antarctic bottom water formation (Fig. 2a,k,l). Convection in the SO then  
148 eventually stops after around 500 years as soon as the AMOC starts to recover and  
149 convection resumes in the North Atlantic (Fig. 2a,b, Fig. A2).

150 The abrupt onset of convection has a pronounced impact also on the carbon cycle  
151 and different biogeochemical tracers in the ocean (Fig. 3). The SO ventilation increases  
152 as a result of both the enhanced convection and the associated sea ice retreat (Fig. 3i).  
153 Consequently, the oxygen content of the interior ocean is replenished by the Southern-  
154 sourced water (Fig. 3l). Meanwhile, large amounts of carbon that were stored mainly  
155 in the deep ocean (Fig. 3o) are brought in contact with the atmosphere, leading to a  
156 rapid release of carbon (Fig. 3f) and an atmospheric  $\text{CO}_2$  increase of  $\sim 15$  ppm in a  
157 few centuries (Fig. 1j).

158 Rhodes et al. (2015) [29] suggested that the jump in  $\text{CH}_4$  seen in core records  
159 during Heinrich Stadial 1 reflects the beginning of the H event, and this argument has

160 been extended also to previous H events [54]. However, our results show that the CH<sub>4</sub>  
161 jump in the middle of the HSs rather reflects the timing of the onset of convection  
162 in the SO, which is delayed by many centuries relative to the start of the actual H  
163 event. In our simulation the CH<sub>4</sub> increase following convection onset in the SO is  
164 mainly a consequence of larger emissions from the tropics (Fig. A1i) which is explained  
165 by a combination of a general increase in precipitation over SH land (Fig. A1c) and  
166 an increase in net primary production due to CO<sub>2</sub> fertilisation (Fig. A1f) with a  
167 consequent increase in substrate available for anaerobic microbial decomposition in  
168 wetland areas (dotted vs solid lines in Fig. 11).

169 The convection process in the SO also induces a large vertical mixing of nutrients  
170 that stimulates primary productivity in the ocean (Fig. A1f), as confirmed also by  
171 proxy records [36].

172 Overall, the sudden onset of convection in the SO shown by the model can consis-  
173 tently explain the peculiar temporal dynamics seen in different proxy records during  
174 Heinrich Stadials.

## 175 4 The bipolar convection seesaw

176 The term bipolar seesaw has been originally introduced by Broecker (1998) [55], who  
177 proposed an anti-phase response of deep sea ventilation in the northern Atlantic and  
178 the SO to explain the Antarctic temperature response during the Younger Dryas.  
179 Later, Stocker and Johnsen (2003) [56] introduced the *thermal* bipolar seesaw concept  
180 to explain the temperature response in Antarctica resulting from changes in the AMOC  
181 during glacial times. In their simple and purely thermodynamic model, the changes in  
182 meridional heat transport induced by AMOC changes combine with a heat reservoir in  
183 the SO to produce the Antarctic temperature response to AMOC perturbations. This  
184 simple model has since been widely invoked to explain the relation between Greenland  
185 and Antarctic temperature evolution, and even to construct an 800,000-year synthetic  
186 record of Greenland temperature variability based on Antarctic ice core data [57].  
187 This concept was further refined based on results of climate model simulations [43]  
188 and updated to use Iberian Margin sea surface temperatures instead of Greenland  
189 temperatures [58].

190 However, the thermal seesaw alone can not explain the qualitative differences  
191 between nHSs and HSs, particularly the rapid CO<sub>2</sub> rise during the latter and little  
192 CO<sub>2</sub> changes during the former. Skinner et al. (2020) [34] suggested that convection in  
193 the SO occurred as a response to an AMOC weakening/collapse during HS4 in what  
194 they call a bipolar *ventilation* seesaw [59, 60], which amplified Antarctic warming and  
195 the atmospheric CO<sub>2</sub> response. However, they do not relate the SO convection directly  
196 to the H event and can therefore not explain why convection would occur only during  
197 some HSs, but not during nHSs.

198 Here we propose that to explain the observed millennial-scale glacial climate vari-  
199 ability, the bipolar *thermal* seesaw should be complemented by the concept of a bipolar  
200 *convective* seesaw. The former operates during the entire DO cycle, while the latter  
201 operates only during HSs. Both seesaws operate through the AMOC, but in different  
202 ways: the bipolar thermal seesaw operates through the interhemispheric AMOC energy

203 transport, the bipolar convection seesaw operates through a general de-stratification  
204 of the ocean caused by the AMOC collapse (Fig. 4) as follows. The reduced northward  
205 heat and salt transport in the Atlantic following the AMOC collapse leads to a warm-  
206 ing and a salinity pile-up in the upper South Atlantic (Fig. A3b,e), as seen also in  
207 other models [43, 61]. The reduced upwelling due to a weaker global overturning cir-  
208 culation following the AMOC collapse causes a general decrease of sub-surface salinity  
209 and increase in surface salinity in the ocean (Fig. A3e). At the same time, substantial  
210 sub-surface warming occurs (Fig. A3b), but with little changes in sea surface tem-  
211 peratures, which are constrained by negative feedbacks through the atmosphere. As  
212 a consequence there is a general increase in surface density due to increased sea sur-  
213 face salinity (Fig. 4b) and a decrease in sub-surface density through a combination of  
214 warming and decrease in salinity (Fig. 4a,c, Fig. A3h). This creates an increasingly less  
215 stable stratification of the global ocean (Fig. 4d) that eventually leads to convective  
216 instability in the SO, the region that is initially closer to neutral density stratification  
217 (Fig. 4e). Salinity is the dominant factor in the de-stratification of the SO (Fig. A4).

218 Convection in the SO is then sustained by an increased southward ocean heat trans-  
219 port in the SO (Fig. A5a,c), caused by the stronger overturning circulation resulting  
220 from the enhanced Antarctic deep water formation (Fig. 2l, 3i). While the sea sur-  
221 face is efficiently cooled by the atmosphere, the sub-surface warming resulting from  
222 the increased heat transport keeps convection going. As soon as the H event ends,  
223 the AMOC slowly starts to recover (Fig. 2a), increasing also the northward ocean  
224 heat transport and consequently decreasing the southward heat transport in the SH  
225 (Fig. A5c,d) until convection can not be sustained anymore in the SO (Fig. A2). The  
226 AMOC recovery is therefore the ultimate cause of the convection stop in the SO. This  
227 is confirmed also by additional simulations where the Heinrich event is extended in  
228 time, leading to a longer persistence of the AMOC off state (Fig. A6c). Convection  
229 in the SO always remains active until the eventual recovery of the AMOC, keeping  
230 CO<sub>2</sub> levels and Antarctic temperature high for this whole time period (Fig. A6f,i).  
231 The convective bipolar seesaw is thus fully controlled by AMOC dynamics. The quick  
232 resumption of the AMOC after the end of the H event is a result of its mono-stability  
233 under the considered boundary conditions.

234 Our model explains why SO convection was triggered only during some HSs, when  
235 freshwater input was large enough to cause an AMOC collapse, but not during regular  
236 nHSs, during which the AMOC was weak but not in an off state and deep water  
237 formation continued, although at a reduced rate, in parts of the North Atlantic.

## 238 5 Discussion

239 We have presented climate model simulations producing deep convection in the SO as  
240 a response to H events in the North Atlantic. When a plausible H event is embedded in  
241 the internal DO-variability, the model reproduces many of the observed features seen  
242 in proxy data for different HSs during the last glacial period, including the exception-  
243 ally rapid Antarctic warming and abrupt and large increase in atmospheric CO<sub>2</sub>. Our  
244 results suggest that understanding of inter-hemispheric interactions associated with

245 glacial climate variability requires a combination of the well-established thermal bipolar  
246 seesaw concept, which is well suited for DO variability, and our newly proposed  
247 convective bipolar seesaw concept, which is required for the response to H events.

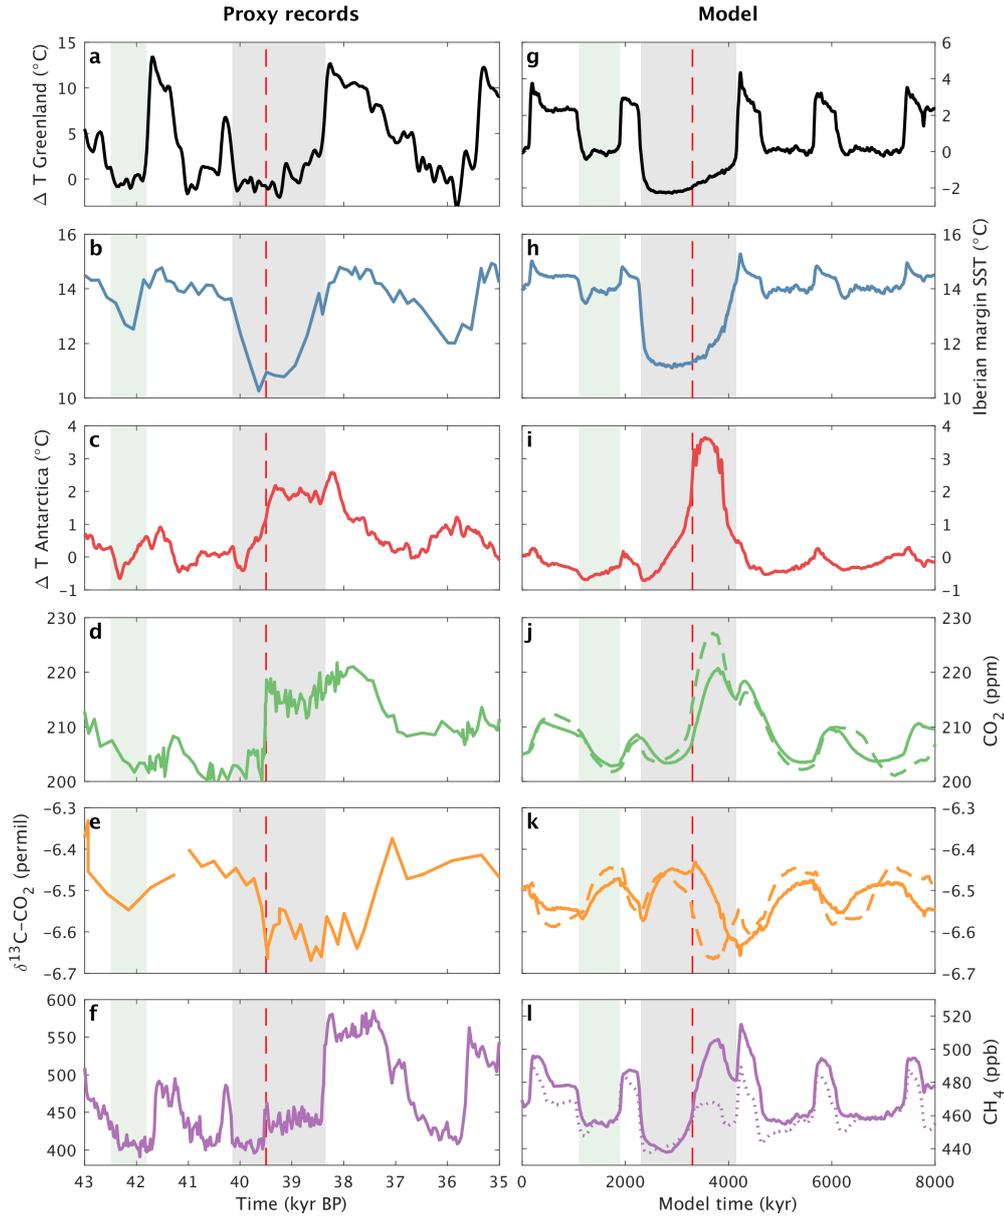

248 While the general CO<sub>2</sub> and CH<sub>4</sub> increases during HSs are explained by SO CO<sub>2</sub>  
249 release and increases in CH<sub>4</sub> emissions from wetlands, both a consequence of the  
250 sudden onset of SO convection, CO<sub>2</sub> and CH<sub>4</sub> emissions from substantial increases in  
251 biomass burning [62], induced by shifts in precipitation as a response to the start of  
252 convection in the SO, could have contributed to the very rapid initial increases and  
253 temporary overshoots seen in CO<sub>2</sub> and CH<sub>4</sub> ice core data during some HSs.

254 A latitudinal shift or change in intensity of the westerlies has been extensively  
255 discussed as possible explanation of the peculiar SH climate response during HSs  
256 [8, 36–38]. In our model the SH westerlies are instead weakening and shifting slightly  
257 southward during HSs (Fig. A7a,b) and a simulation with fixed wind stress shows that  
258 changes in the westerlies play a negligible role in the onset of convection in the SO  
259 (Fig. A7c,d,e).

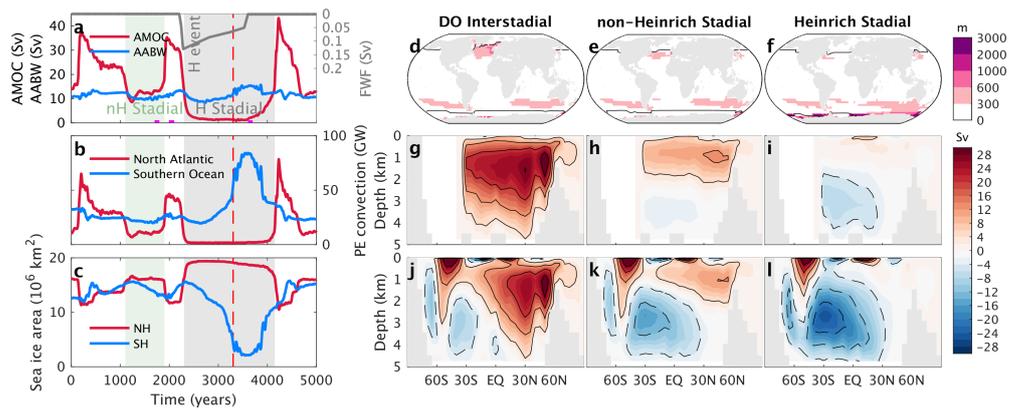

260 Generally, reconstructions indicate that the magnitude of ice discharge during dif-  
261 ferent Heinrich events was potentially quite different [24]. The response in many proxies  
262 is large during some HSs, e.g. HS4, HS5 and HS1, but is less apparent during e.g. HS2  
263 and HS3, possibly because these Heinrich events were weaker, and the lower freshwater  
264 input did not cause a complete collapse of the AMOC and therefore failed to trigger  
265 convection in the SO. This is supported by model simulations where the freshwater  
266 hosing is reduced by a factor of two, in which case the AMOC is still substantially  
267 weakened, but widespread convection is not triggered in the SO (Fig. A6b,e,h).

268 The bipolar convection seesaw is a robust feature of our model. It does not depend  
269 on the timing of the H event during the DO cycles (Fig. A6a,d,g) and is relatively  
270 insensitive to model parameters (Fig. A8). It also works under very different boundary  
271 conditions in terms of CO<sub>2</sub> and ice sheets (Fig. A9), but the AMOC becomes more  
272 stable with increasing size of the NH ice sheets, meaning that an increasingly larger  
273 freshwater flux is needed to collapse the AMOC and trigger convection in the SO.

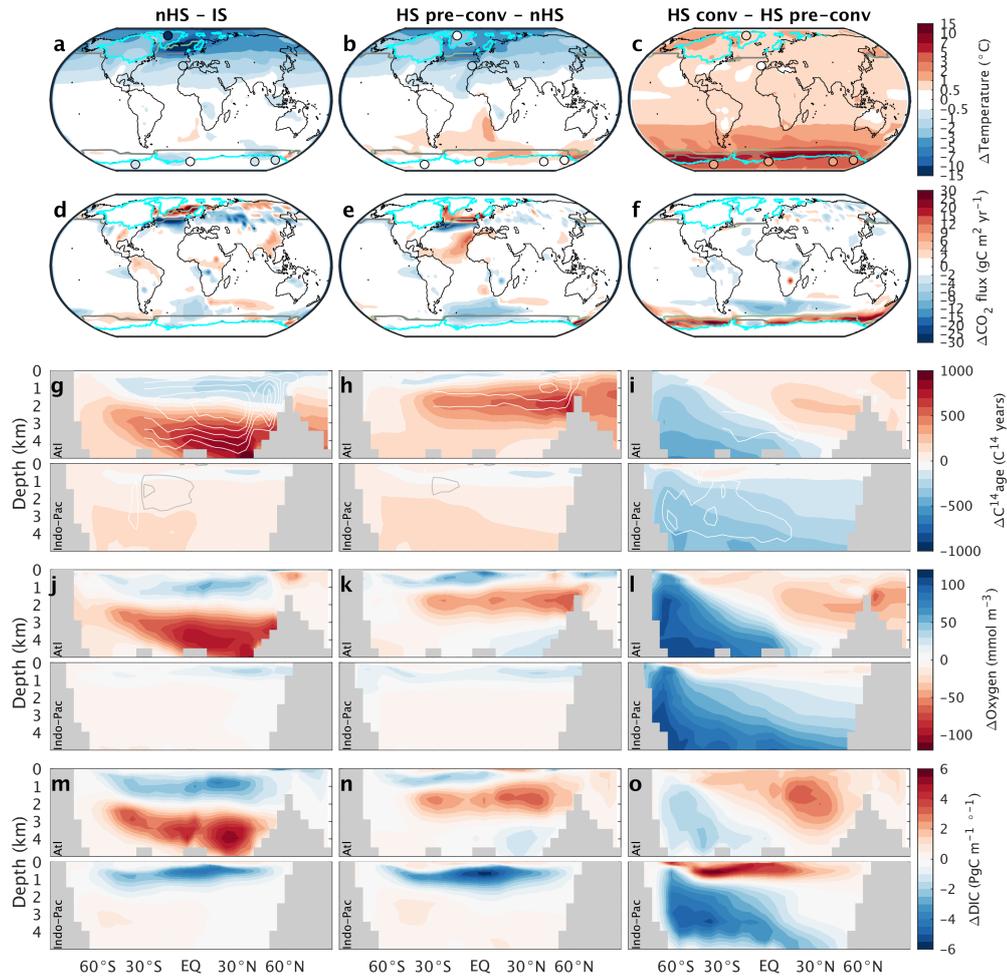

274 The robustness of the proposed bipolar convection seesaw with respect to different  
275 climate and boundary conditions suggests that it could also operate as a response  
276 to a possible future collapse of the AMOC under global warming, with potentially  
277 large impacts on regional and global climate and the Antarctic ice sheet. We suggest  
278 that Southern Ocean convection should be considered as a tipping element in the  
279 Earth system, with the bipolar convection seesaw forming a previously unidentified  
280 potential cross-hemispheric link between different tipping elements and more generally  
281 connecting ocean circulation, carbon cycle and ice sheets.

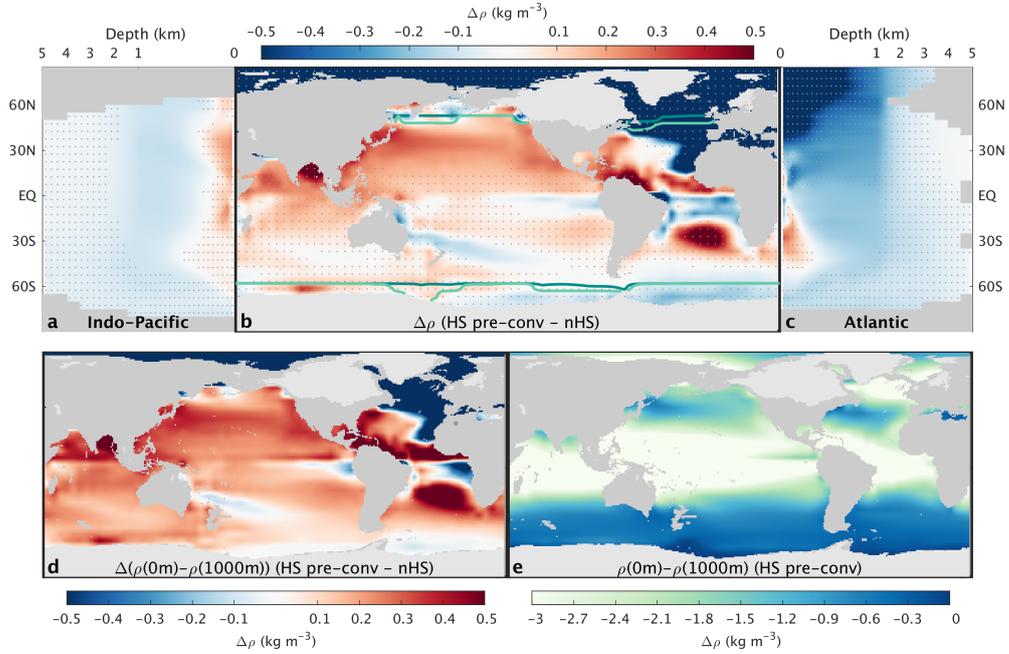

**Fig. 1 Proxy-model comparison of millennial climate variability.** Comparison of simulated climate variability under typical mid-glacial conditions with proxy reconstructions of a time interval around Heinrich Stadial 4. Simulated and reconstructed **a,g** Greenland temperature [4], **b,h** Iberian Margin sea surface temperature [5], **c,i** Antarctic temperature averaged over four ice cores (WDC, EDC, EDML and TALDICE) [28], **d,j** atmospheric CO<sub>2</sub> concentration [7, 8], **e,k**  $\delta^{13}C$  of atmospheric CO<sub>2</sub> [51] and **f,l** atmospheric CH<sub>4</sub> concentration [29]. Proxy records are shown in the left column and model simulation results in the right column. The dashed lines in **j,k** show results of a model simulation where the land carbon cycle is not active and only ocean and atmosphere interact to determine atmospheric CO<sub>2</sub>. The  $\delta^{13}C$  age scale in **e** is shifted by -160 years following ref.[8]. The dotted line in **l** shows CH<sub>4</sub> concentration in a simulation with a prescribed constant CO<sub>2</sub> of 205 ppm and thus represents the simulated CH<sub>4</sub> evolution in the absence of the CO<sub>2</sub> fertilisation effect. The shaded areas indicate the Heinrich Stadial (grey) and a non-Heinrich Stadial (green). The vertical red dashed lines mark the timing of the jump in CH<sub>4</sub> and CO<sub>2</sub> in the left column and the onset of convection in the Southern Ocean in the right column.

**Fig. 2 The bipolar convection seesaw.** North Atlantic versus Southern Ocean climate evolution in model simulations for mid-glacial conditions with internally generated DO events and a prescribed Heinrich event. **a**, Time series of the maximum of the Atlantic meridional overturning streamfunction (red), Antarctic bottom water formation rate (blue) and freshwater flux applied to represent a Heinrich event in the North Atlantic (grey). **b**, Time series of the potential energy released by convection in the North Atlantic (north of the Equator) and the Southern Ocean (south of 55°S). **c**, Time evolution of the maximum sea ice area in the two hemispheres. The shaded areas in **a-c** indicate the Heinrich Stadial (HS) and a non-Heinrich Stadial (nHS). **d-f**, Maximum mixed layer depth for three time intervals marked by the magenta intervals in **(a)** representing DO Interstadial (**d**), nHS (**e**) and HS (**f**) conditions. The vertical red dashed lines mark the onset of convection in the Southern Ocean. Black lines indicate the maximum sea ice extent. For the same three time periods the Atlantic (**g-i**) and global (**j-l**) meridional overturning streamfunctions are also shown.

**Fig. 3** Climate and ocean biogeochemistry changes during DO and H events. Differences in simulated variables between non-Heinrich Stadial and Interstadial (left), Heinrich Stadial before the onset of convection in the Southern Ocean and non-Heinrich Stadial (middle) and Heinrich Stadial after and before the onset of convection (right) for **a-c** annual mean near-surface air temperature, **d-f** net carbon flux to the atmosphere, **g-i** zonally averaged radiocarbon ventilation age **j-l** zonally averaged oxygen concentration and **m-o** zonally integrated dissolved inorganic carbon content. The filled circles in **a-c** represent temperature changes estimated from proxy records [4, 5, 28]. All ocean fields in **g-o** are shown separately for the Atlantic Ocean and the Indo-Pacific Oceans, with the Southern Ocean sectors being included. The contours in **g-i** indicate changes in the ocean overturning streamfunctions, negative for white contours and positive for grey contours, plotted at intervals of 4 Sv.

**Fig. 4 Bipolar seesaw mechanism.** **a-c** Density differences between the HS prior to the onset of convection in the SO and average nHS conditions at **b** the surface and as zonal average of **a** the Indo-Pacific Oceans and **c** the Atlantic Ocean. The dots indicate regions where the density difference is dominated by changes in salinity, as opposed to temperature changes. The lines in **b** indicate the maximum sea ice extent during the nHS (dark cyan) and the HS prior to convection (green). **d** Change in density difference between the surface and 1000 m depth during the HS prior to convection onset relative to average nHS conditions. **e** Density difference between the surface and 1000 m depth during the HS prior to convection.

## 282 6 Methods

### 283 6.1 Earth system model

284 We use the CLIMBER-X Earth system model [52, 53], including the frictional-  
285 geostrophic 3D ocean model GOLDSTEIN [63, 64] with 23 vertical layers, the  
286 semi-empirical statistical-dynamical atmosphere model SESAM [52], the dynamic-  
287 thermodynamic sea ice model SISIM [52], the land surface model with interactive  
288 vegetation PALADYN [65] and the ocean biogeochemistry model HAMOCC6 [66–  
289 68]. The comprehensive carbon cycle in the model allows to interactively compute the  
290 atmospheric CO<sub>2</sub> evolution. Here we employ the 'closed' carbon cycle setup, in which  
291 marine sediments and chemical weathering on land are ignored. In this setup carbon is  
292 conserved in the atmosphere-ocean-land system, which is a reasonable assumption on  
293 millennial scales. All components of the model have a horizontal resolution of 5°×5°.  
294 Ice sheets are prescribed at their modern state and the net freshwater flux from ice  
295 sheets is zero. The model is described in detail in ref. [52] and ref. [53] and in general  
296 shows performances that are comparable with state-of-the-art CMIP6 models under  
297 different forcings and boundary conditions. Notably, the model has been shown to  
298 reproduce DO-like variability under mid-glacial conditions [16] and the stability of the  
299 AMOC in the model has been thoroughly explored [69].

### 300 6.2 Experiments

301 The main model experiment is designed to simulate realistic millennial-scale climate  
302 variability during glacial times, i.e. Marine Isotope Stage 3. The boundary conditions  
303 for this simulation include mid-glacial ice sheets from the GLAC-1D reconstruction  
304 [70], a CH<sub>4</sub> concentration of 450 ppb, a N<sub>2</sub>O concentration of 240 ppb and present-  
305 day orbital parameters. Similarly to ref. [16] we apply noise in the surface freshwater  
306 flux in the northern North Atlantic so that the model produces robust internal DO  
307 cycles. We first perform a model spinup of 10,000 years with a prescribed atmospheric  
308 CO<sub>2</sub> concentration of 205 ppm, to allow the climate and carbon cycle to reach an  
309 (oscillating) equilibrium state. Starting from that we then run a 8,000 years long simu-  
310 lation with interactive CO<sub>2</sub>. In this simulation we introduce a plausible Heinrich event  
311 starting in the year 2200, during a DO Interstadial phase. The prescribed temporal  
312 shape of the freshwater flux associated with the Heinrich iceberg discharge event is  
313 derived qualitatively using results of different ice sheet model simulations [17, 19, 71],  
314 with a peak freshwater flux of 0.13 Sv, followed by a gradual decline until the event  
315 ends around 1200 years later (Fig. 2a). Spatially, the freshwater flux is added uni-  
316 formly to the IRD belt in the North Atlantic, between 40 and 60°N and between 10  
317 and 70°W. No compensation of the freshwater flux is applied and the average ocean  
318 salinity decreases by ~0.1 psu by the end of the H event.

319 In addition to this reference model simulation we have performed a number of  
320 simulations to explore the sensitivity of the results to the amplitude (half and double),  
321 timing (H event starting at the beginning and in the middle of a Stadial) and duration  
322 of the H event (idealized constant 0.1 Sv freshwater flux for 1000, 2000, 3000 and 4000  
323 years).

324 We also run an ensemble of simulations with perturbed parameters to assess the  
325 robustness of the results with respect to changes in ocean model parameters (minimum  
326 and maximum diapycnal diffusivities, Gent-McWilliams diffusivity and the maximum  
327 slope of the isopycnals). In order to avoid having to run a spinup of the carbon cycle for  
328 each of the ensemble members, these experiments are run with a prescribed constant  
329  $\text{CO}_2$  of 205 ppm, starting from the same initial condition as the reference run and the  
330 H event is applied starting from the year 3000.

331 To investigate the robustness of our results to changes in boundary conditions,  
332 we have performed additional simulations with present-day and last glacial maximum  
333 (LGM) ice sheets and with different constant  $\text{CO}_2$  concentrations (180, 220 and 280  
334 ppm). These simulations are run for 10,000 years and the H event is applied starting  
335 in the year 5000, to give the system enough time to equilibrate with the different  
336 boundary conditions. The initial condition for these experiments is a pre-industrial  
337 equilibrium state. We have also repeated these simulations with halving and doubling  
338 of the amplitude of the H event.

339 To separate the effect of changes in wind stress over the ocean on the model  
340 response to DO and H events, we have run an additional simulation in which the  
341 seasonal wind stress fields are kept constant at their initial (non-Heinrich Stadial)  
342 state.

343 To quantify the effect of  $\text{CO}_2$  fertilisation on the increase in  $\text{CH}_4$  emissions following  
344 the onset of SO convection, we have performed an additional simulation with the same  
345 boundary conditions as the reference model run, but in which atmospheric  $\text{CO}_2$  is  
346 prescribed at a constant value of 205 ppm.

347 **Acknowledgements.** MW is funded by the German climate modelling project  
348 PalMod supported by the German Federal Ministry of Education and Research  
349 (BMBF) as a Research for Sustainability initiative (FONA) (grant nos. 01LP1920B,  
350 01LP1917D, 01LP2305B). CK is funded by the Bundesgesellschaft für Endlagerung  
351 through the URS project (research project no. STAFuE-21-4-Klei). BL is supported by

357 tion to the Center for Earth System Research and Sustainability (CEN) of Universität  
358 Hamburg), as well as the European Union’s Horizon 2020 research and innovation  
359 programme 4C (grant no. 821003). The authors gratefully acknowledge the European  
360 Regional Development Fund (ERDF), the German Federal Ministry of Education and  
361 Research and the Land Brandenburg for supporting this project by providing resources  
362 on the high performance computer system at the Potsdam Institute for Climate Impact  
363 Research.

## 364 **Declarations**

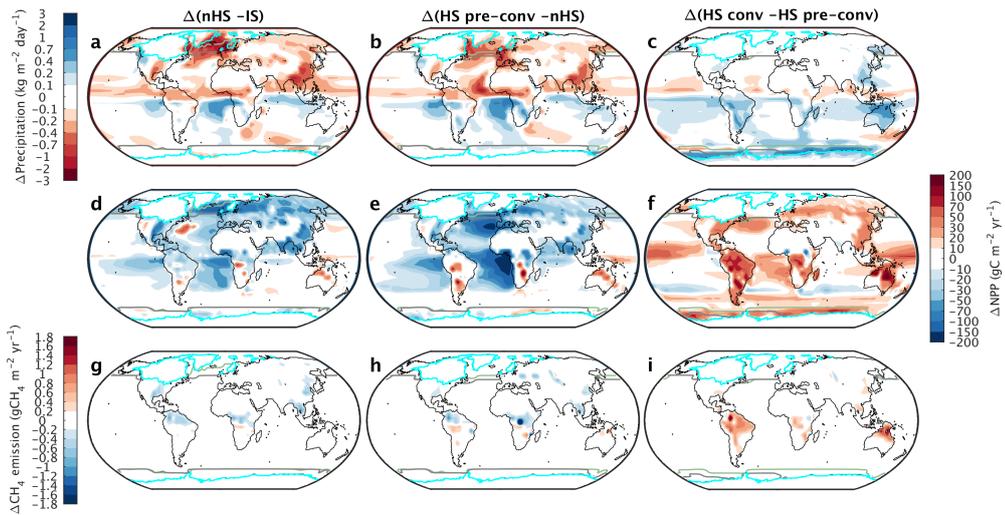

365 **Competing interests.** The authors declare no competing interests.

366 **Data availability.** The output of the reference model simulation is available on  
367 Zenodo at: <https://doi.org/10.5281/zenodo.14710066>.

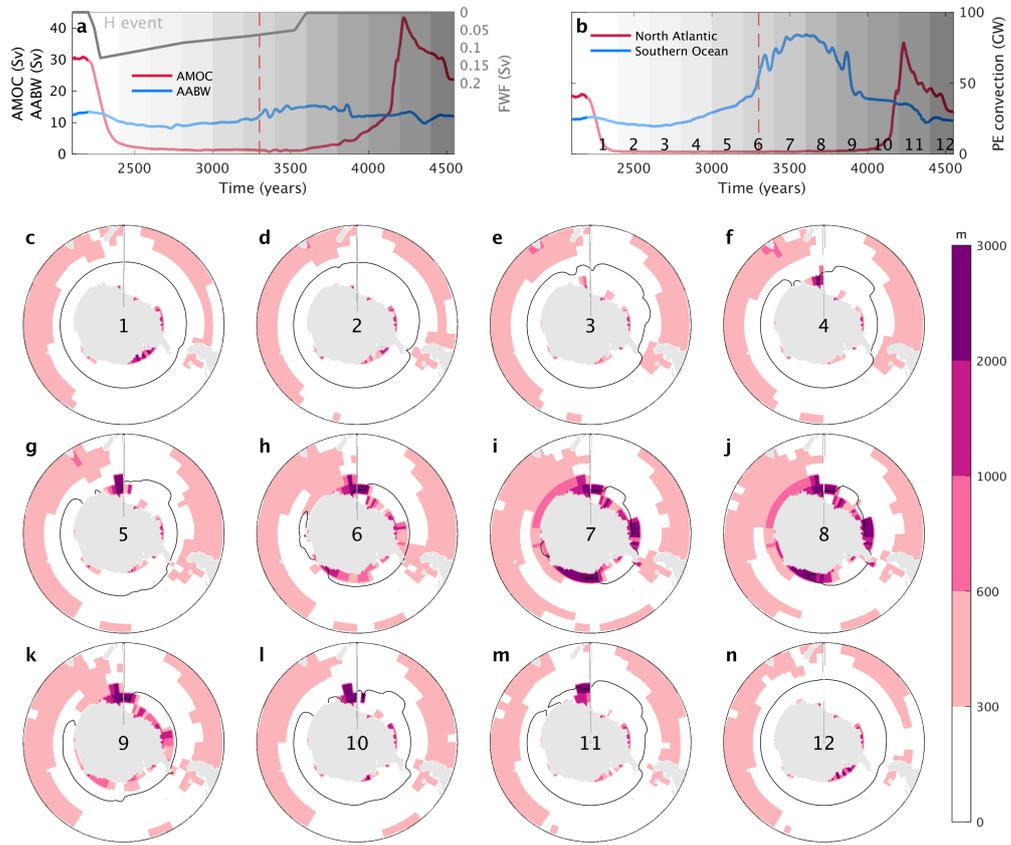

368 **Code availability.** The CLIMBER-X model code is available at  
369 <https://github.com/cxesmc/climber-x>. For this study we used the tagged version  
370 v1.3.0 of the model.

371 **Author contribution.** M.W. and A.G. conceived the study. M.W. designed and  
372 performed the model simulations. All authors contributed to the analysis and  
373 discussion of the results and the writing of the paper.

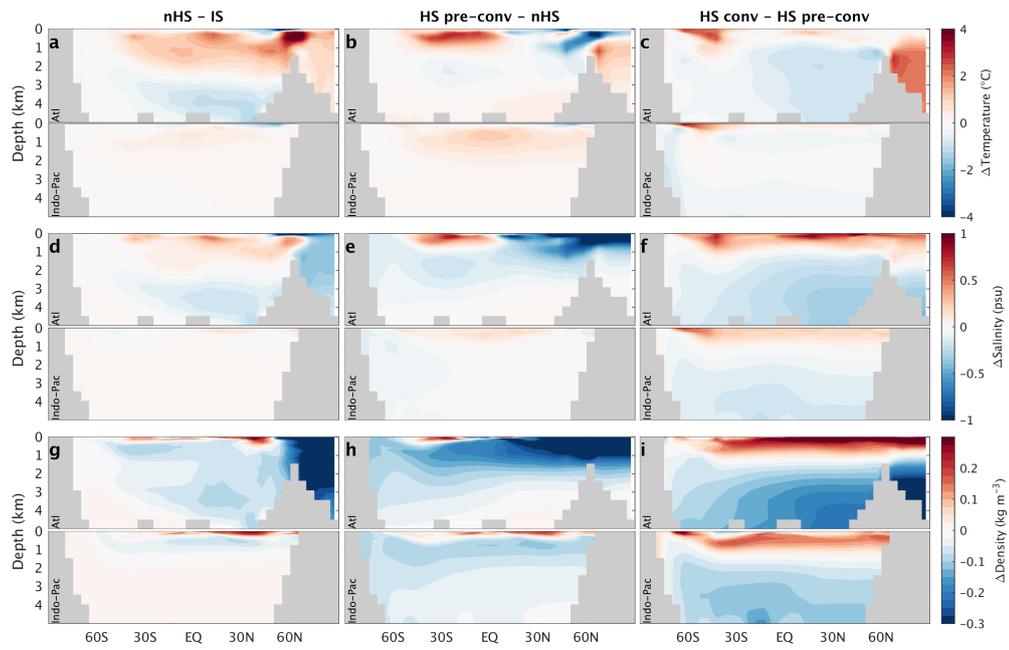

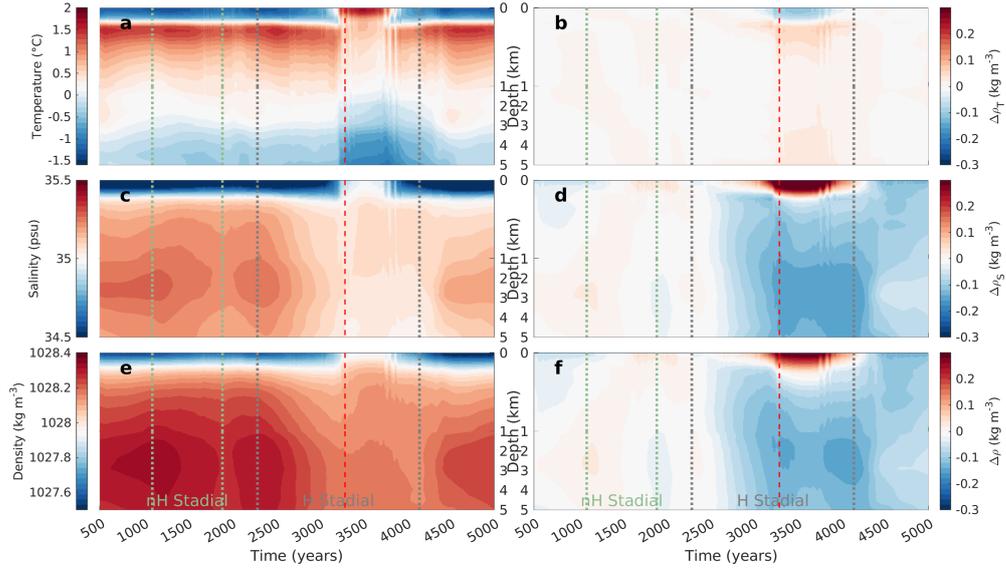

**Fig. A1** Changes in precipitation, net primary productivity and  $\text{CH}_4$  emissions between different time slices during the DO/H cycles. Same as Fig. 3a-c, but for a-c annual precipitation, d-f net primary productivity on land and the ocean and g-i natural  $\text{CH}_4$  emissions from wetlands.

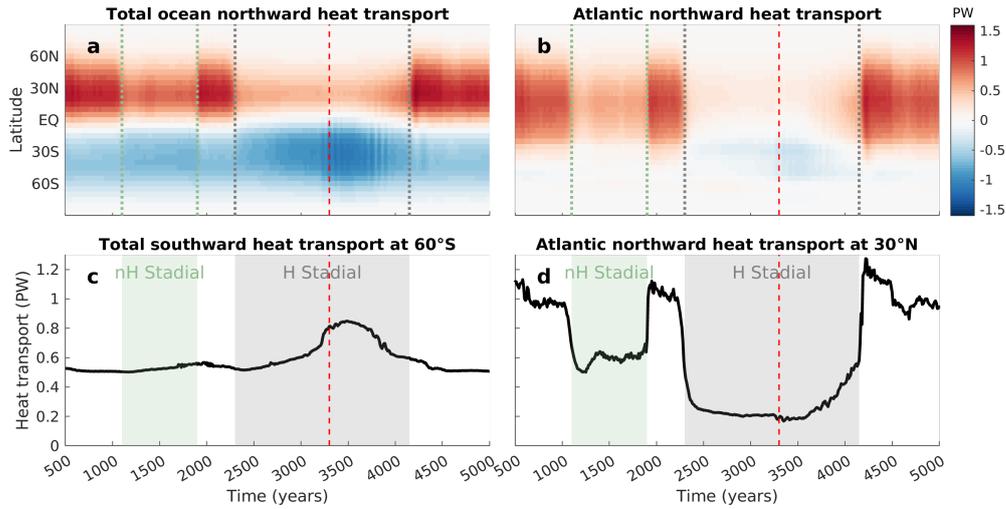

**Fig. A2 Evolution of the maximum mixed layer depth in the SO during the HS. c-n** Maximum mixed layer depth in the SO at different times during the HS, corresponding to the numbers and shaded grey bars as indicated in **a,b**. Panels **a,b** are the same as those in Fig. 2.

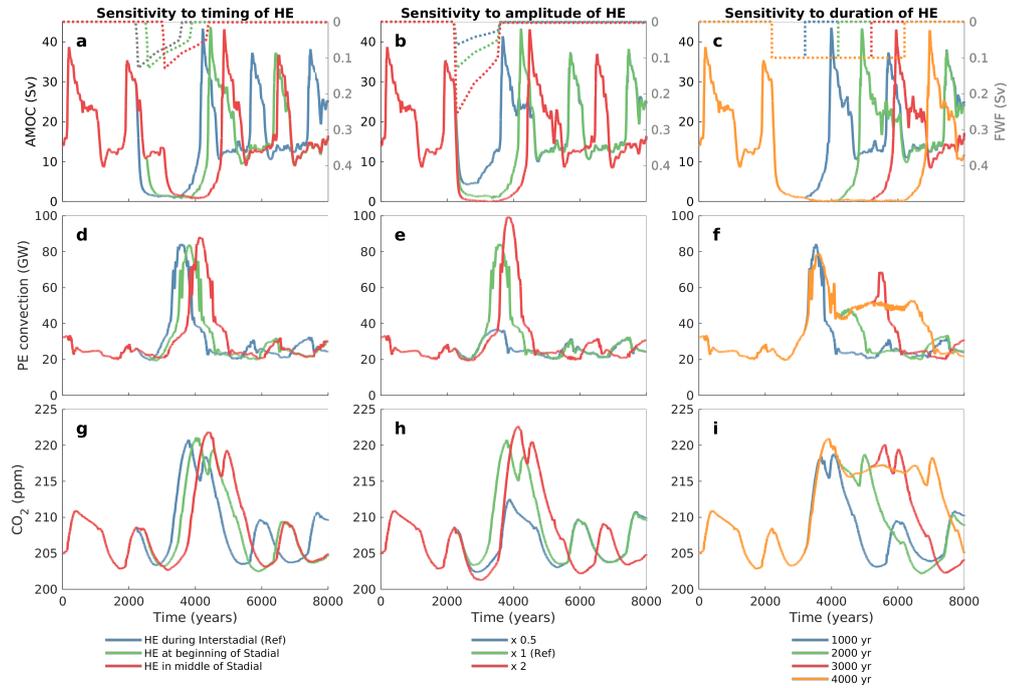

**Fig. A3 Changes in ocean temperature, salinity and density.** Zonally averaged potential temperature, salinity and density differences between different time periods: (left) nHS relative to Interstadial, (center) HS prior to convection onset in the SO relative to nHS and (right) after convection onset relative to before convection start. All fields are shown separately for the Atlantic Ocean and the Indo-Pacific Oceans, with the Southern Ocean sectors being included.

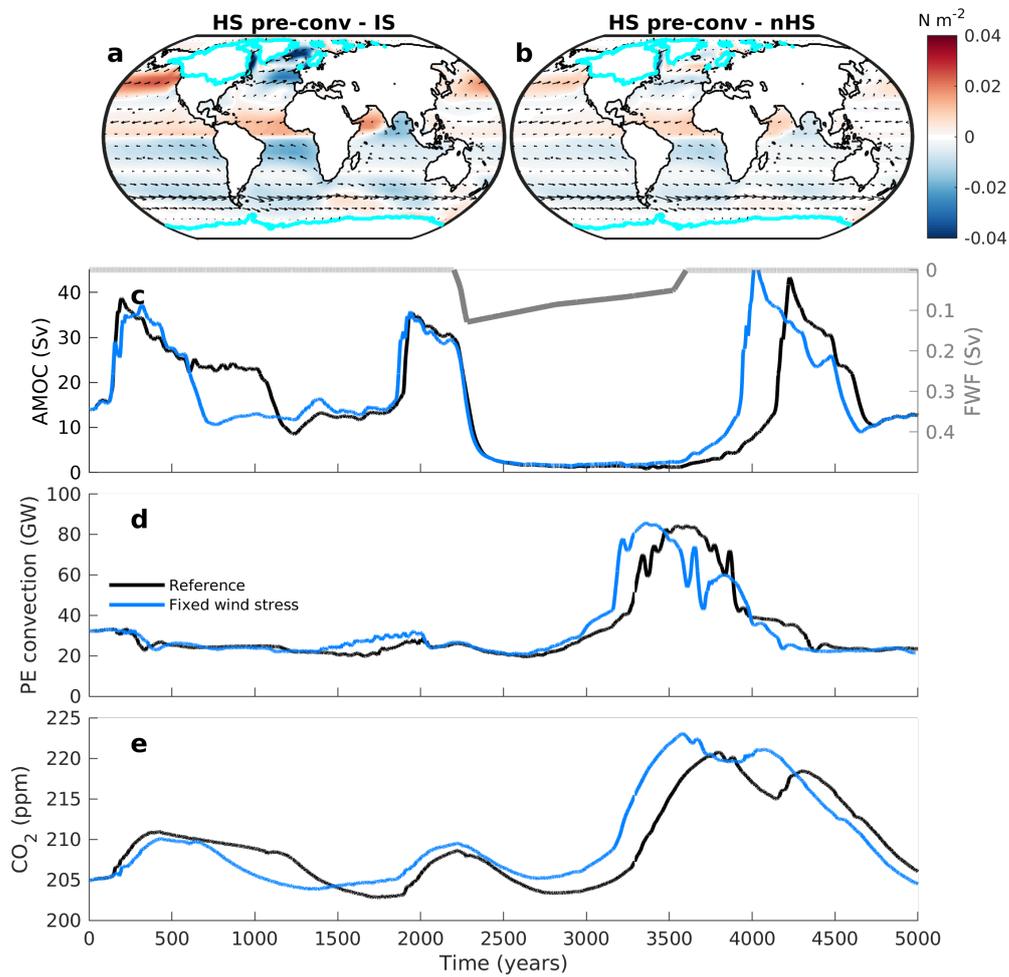

**Fig. A4 Ocean temperature, salinity and density evolution in the Southern Ocean.** Temporal evolution of vertical profiles of **a** temperature, **c** salinity and **e** density averaged over the Southern Ocean south of 60°S, excluding the Atlantic sector. The right panels show the contributions of **b** temperature and **d** salinity changes relative to average nHS conditions to density changes. The total density changes relative to average nHS conditions are shown in **f**.

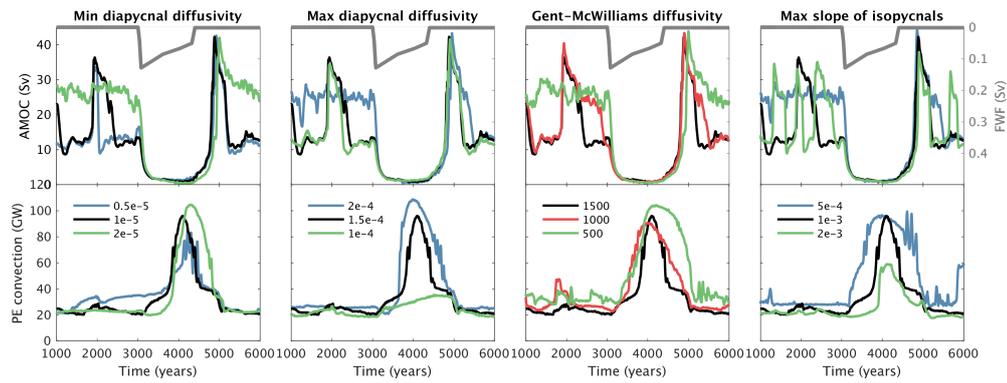

**Fig. A5 Evolution of meridional ocean heat transport.** **a** Meridional ocean heat transport as a function of time, **b** evolution of the meridional heat transport by the Atlantic over time, **c** evolution of southward ocean heat transport at 60°S and **d** northward heat transport at 30°N in the Atlantic. The timing of the non-Heinrich Stadial and the Heinrich Stadial are marked in the panels and the vertical red dashed line indicates the timing of the onset of convection in the Southern Ocean.

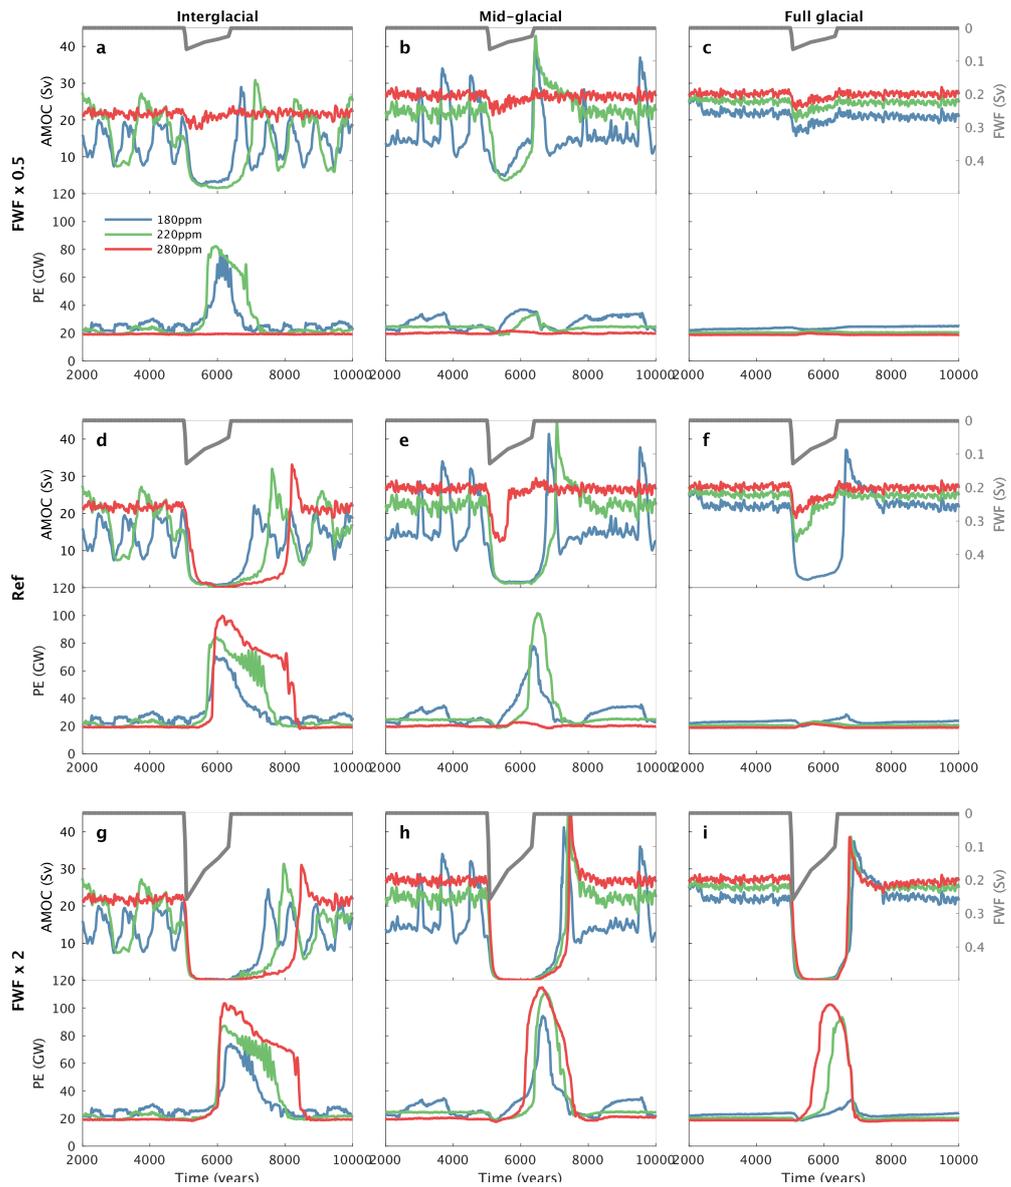

**Fig. A6 Sensitivity to timing, amplitude and duration of Heinrich event.** Dependence of the simulated AMOC, potential energy released by convection in the Southern Ocean, and atmospheric CO<sub>2</sub> to **a,d,g** the timing, **b,e,h** the amplitude, and **c,f,i** the duration of the Heinrich Event. The dotted lines in the top panels show the freshwater hosing flux applied to the North Atlantic to mimic the different Heinrich events. The legends at the bottom provide the color code for the different lines.

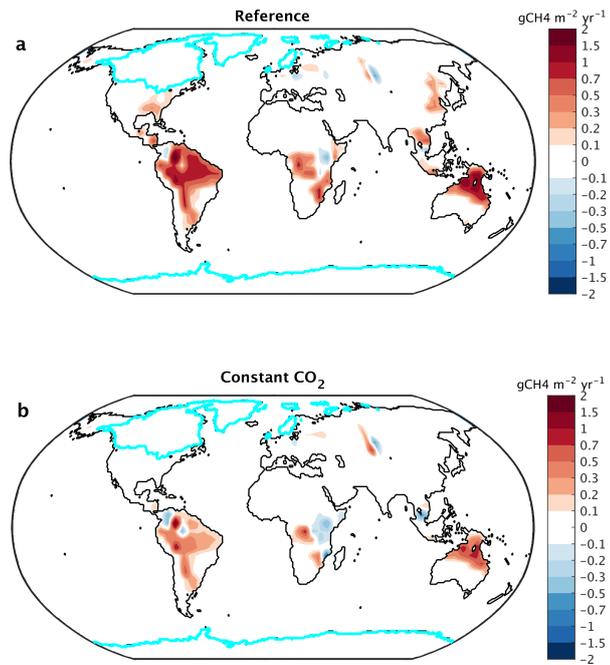

**Fig. A7 Sensitivity to wind stress.** Changes in simulated wind stress over the ocean between Heinrich Stadial prior to the onset of convection in the Southern Ocean and **a** DO Interstadial and **b** non-Heinrich Stadial. Comparison of simulated evolution of **c** maximum of the Atlantic meridional overturning streamfunction, **d** potential energy released by convection in the Southern Ocean and **e** atmospheric CO<sub>2</sub> in the reference run (black) and in a simulation where the (seasonally varying) wind stress over the ocean is prescribed to average non-Heinrich Stadial conditions (blue).

**Fig. A8 Sensitivity to ocean model parameters.** Dependence of the simulated AMOC and potential energy released by convection in the Southern Ocean to the minimum (surface) value of diapycnal diffusivity ( $m^2s^{-1}$ ), the maximum (deep ocean) value of diapycnal diffusivity ( $m^2s^{-1}$ ), the Gent-McWilliams diffusivity ( $m^2s^{-1}$ ) and the maximum slope of the isopycnals. The values of the parameters used are given in the legends in the bottom panels. All the experiments are for the same boundary conditions corresponding to the reference model simulation presented in the paper.

**Fig. A9 Sensitivity to ice sheets and baseline atmospheric CO<sub>2</sub> for different amplitudes of the Heinrich event.** Maximum of the AMOC streamfunction and potential energy released by convection in the SO for model simulations with interglacial (present-day) ice sheets (left), mid-glacial ice sheets (middle) and full glacial (LGM) ice sheets (right) with different amplitudes of the H event (increasing from top to bottom) and different prescribed constant CO<sub>2</sub> concentrations (180, 220 and 280 ppm) as indicated by the colored lines and the legend.

**Fig. A10 Changes in CH<sub>4</sub> emissions following SO convection onset.** Differences in natural emissions of CH<sub>4</sub> from wetlands between after and before the onset of convection in the SO during the HS in **a** the reference model simulation and **b** an experiment where the CO<sub>2</sub> fertilisation effect is suppressed in the model by prescribing a constant atmospheric CO<sub>2</sub> concentration of 205 ppm in the simulation.
