## Abstract

Variable hydrometeorological conditions can impact electric utilities' financial stability. Extreme temperatures often increase electricity demand, raising utility costs, while drought reduces hydropower generation and often reduces revenues, with financial impacts potentially exacerbated by spikes in fuel prices, particularly natural gas. In this study, a model of the U.S. West Coast power system is combined with a financial risk model of a large California electric utility as it responds to variable hydrometeorology and market conditions,

and is used to test the performance of a novel financial tool for managing risk. An insurance contract based on a composite index of measures related to streamflow, temperature, and natural gas prices is developed and its cost-effectiveness is compared against a portfolio of three currently available index contracts each based on a single index. The new composite index contract achieves an equivalent reduction in the utility's net revenue variance as a portfolio of the three existing contract types for roughly half the cost with the cost reduction largely attributable to lower basis risk associated with the composite index contract. The utility's financial risk and the effectiveness of the new contract are also explored under an alternative regulatory scenario involving a pollution tax intended to reduce air pollution damages and emissions. Overall, this case study represents a new approach to managing financial risk arising from hydrometeorological and market variability for vertically integrated utilities, the most common utility structure.

## 1 Introduction

Variable hydrometeorological conditions, particularly in the form of drought and extreme temperatures, expose electric utilities to financial risk in the form of intermittent reductions in generation and increases in electricity demand, which combine to force greater reliance on more expensive generation [Bates et al., 2008, McMahan and Gerlak, 2020, Gleick, 2017]. For example, electric utilities with significant hydropower assets experience decreased generation due to reduced reservoir inflows during drought [Bates et al., 2008, Blomfield and Plummer, 2014]. Deviations from expected temperatures, such as cooler than expected summers or warmer winters, can also substantially reduce revenues based on

11 electricity demand, the majority of which is driven by the heating and cooling of  
12 buildings [Comstock, 2018, Serzan, 2019]. Similarly, extremely high or low tem-  
13 peratures lead to large spikes in demand that a utility must often meet via the  
14 use of more expensive, generation or reliance on market purchases during high  
15 price periods. As these fluctuations are related to weather, both their intermittent  
16 nature and unpredictable severity present utilities with financial uncertainty.

17 Further exacerbating these challenges is the often correlated nature of droughts  
18 and heat waves, raising the probability that periods of low electricity supply and  
19 high demand will occur simultaneously [AghaKouchak et al., 2014]. This com-  
20 bination of environmental events can force electric utilities to fall back on al-  
21 ternative generation sources that are not only much more expensive, but also  
22 significantly more polluting, as is the case in California and even in other grids,  
23 where older, less efficient thermal generation is used as a last resort (Figure S1).

24 California's electric utilities have recently experienced acute financial impacts  
25 from variable hydrometeorology [DiSavino, 2021]. During California's 2012-2016  
26 drought, high temperatures led to increased electricity demand necessitating re-  
27 liance on more expensive power sources, which cost the state's three largest  
28 investor-owned utilities an additional \$3.8 billion, while lost hydropower genera-  
29 tion accounted for another \$1.9 billion in losses [Kern et al., 2020]. The increased  
30 use of thermal power during these hydrometeorological extremes also had an  
31 impact on public health in California, as these more expensive sources are also  
32 more polluting and increase air pollutant emissions, raising questions about how

33 these spikes in emissions could be reduced [Gleick, 2017, Herrera-Estrada et al.,  
34 2018].

35 While extreme weather events pose many operational challenges for electric  
36 utilities in terms of supply reliability, there is also growing attention to the fi-  
37 nancial risks associated with the attendant intermittent swings in costs and rev-  
38 enues [Allianz SE, 2013]. Traditional financial risk management tools, such as  
39 reserve funds and lines of credit, often prove effective for managing more mod-  
40 erate hydro-meteorological fluctuations, but the growing frequency and severity  
41 of these events has utilities searching for more innovative tools and strategies  
42 [Larson et al., 2012, Meenan et al., 2019]. This has resulted in greater interest  
43 in financial risk transfer instruments, such as index-based insurance, which has  
44 been shown to be effective at managing the financial consequences of more ex-  
45 treme events and has even been shown to increase the market value of electric  
46 and gas utilities with weather-related exposure [Pérez-González and Yun, 2013].  
47 Utilities exposed to significant financial risk by hydrometeorological events are  
48 being increasingly scrutinized by investors, lenders, and credit rating agencies  
49 [Moody's, 2013] as such risk can lead to higher interest rates on borrowing, a  
50 critical consideration in the capital intensive electric power sector.

51 Financial contracts in the form of options, forwards or futures are commonly  
52 used in the electric power sector to protect against fluctuations in commod-  
53 ity prices (e.g., natural gas, crude oil, wholesale electricity) [Burger et al., 2014,  
54 Schofield, 2021]. These contracts typically obligate a buyer to purchase or sell

55 a commodity on an agreed upon amount in the future at a predetermined price  
56 [Deng and Oren, 2006, Hull, 2022]. In recent years, index-based insurance con-  
57 tracts have been developed that facilitate payouts to the contract buyer from a  
58 “counterparty” (often an insurer or financial institution) when a specified thresh-  
59 old is crossed on a defined index that serves as a proxy for a financial metric of  
60 concern (e.g., costs, revenues). These types of contracts are often used to man-  
61 age the financial risk of deviations from established hydrometeorological pat-  
62 terns, such as low precipitation [Larson et al., 2012] or extreme temperatures.  
63 These contracts differ from traditional indemnity-based insurance, in which pay-  
64 outs rely on an onsite determination of damages made after a covered loss occurs  
65 (e.g., floods). Index-based insurance can offer a useful alternative by removing the  
66 subjective human element in determining loss while also accelerating the time  
67 to payout, which can sometimes be quite lengthy in the case of indemnity-based  
68 contracts [Meenan et al., 2019]. For example, temperature-based index contracts  
69 are used by electric utilities to manage the unexpected reductions in demand  
70 and the lower revenues that accompany cooler summers and warmer winters  
71 [Artemis, 2022]. Index-based contracts are also commonly applied in agricul-  
72 ture to protect farmers against the financial ramifications of weather-related crop  
73 losses (e.g., drought, extreme temperatures) [Turvey, 2001]. One potential draw-  
74 back to index-based contracts, however, is basis risk, which results when there  
75 is poor correlation between the specified index and financial losses. High basis  
76 risk leads to over- or under-payment relative to the losses, making the instru-

77 ment ineffective and/or expensive. Developing an effective index-based contract  
78 requires maintaining a low level of basis risk by ensuring the index and losses  
79 are strongly correlated [Clement et al., 2018, Woodard and Garcia, 2007].

80 Electric utilities are well-acquainted with the concept of index-based contracts  
81 as risk management tools, having long used temperature-based derivative con-  
82 tracts, as well as those linked to natural gas prices, to manage the related financial  
83 risks. Index-based contracts have more recently also been employed to manage  
84 drought-related financial losses for hydropower producers [Blomfield and Plum-  
85 mer, 2014, The World Bank, 2018], with several recent studies pointing to the  
86 potential for more innovation in this area [Foster et al., 2015, Kern et al., 2015,  
87 Hamilton et al., 2020, Denaro et al., 2018]. Most electricity producers rely on  
88 more than just hydropower; however, their net revenues are influenced by mul-  
89 tiple factors, such that their financial risk management requires consideration of  
90 more than just a single measure. In this case, financial risk management is often  
91 approached by using a portfolio of available single index contracts, which might  
92 include contracts that are separately intended to manage risks related to vari-  
93 ations in temperature, hydrology, and market prices, but more recent research  
94 suggests that a “composite” contract based on a multivariate index could be use-  
95 ful [Kern et al., 2015, Li et al., 2021, Murthy et al., 2022, Shi and Jiang, 2016].  
96 Kern et al. [2015] used a composite index that incorporated consideration of both  
97 hydrologic conditions and natural gas prices, which often correlate well with  
98 wholesale electricity prices in markets where the marginal generators use natu-

99 ral gas, to lower the basis risk of a contract designed to provide risk management  
100 for a hydropower-only generator selling power into an electricity market. More  
101 sophisticated multi-variate composite indices have also been explored in the agri-  
102 cultural sector [Li et al., 2021, Murthy et al., 2022]. Shi and Jiang [2016] demon-  
103 strated that a composite index-based contract could effectively protect farmers  
104 against multiple weather hazards (e.g., rainfall, temperature) that influence rice  
105 yields and suggested it should be less expensive than a portfolio of single index  
106 contracts, but did not explore the question further. Given the multiple weather  
107 hazards and market uncertainty facing electric utilities with many sources of  
108 generation, a composite index-based contract might be developed as a means of  
109 more cost-effectively managing multiple risks.

110 Developing risk management tools for electric utilities with a diverse genera-  
111 tion mix complicates the relationship between drought and revenue loss relative  
112 to that of a hydropower producer by itself. A composite index insurance con-  
113 tract that simultaneously accounts for the risk of compounding hydrometeoro-  
114 logical extremes (e.g., temperature, and drought) could increase the correlation  
115 between the index and a utility's costs and revenues (or considered together, net  
116 revenues), thus lowering basis risk and improving the instrument's performance.  
117 To explore this idea, a composite index insurance contract that considers hydro-  
118 logic conditions, temperature and wholesale natural gas prices is developed in  
119 this study. The performance of the composite index contract and a portfolio of  
120 existing single-index contracts that independently address the same three risks

121 is compared in terms of cost and effectiveness.

122 These two approaches are evaluated using the situation faced by Pacific Gas  
123 and Electric Company (PG&E), a publicly traded utility in California that earns  
124 revenues through the generation, sales, and transmission of electricity. Pacific  
125 Gas & Electric is vulnerable to extreme temperatures and high natural gas prices  
126 in addition to drought [Kern et al., 2020], such that a composite index considering  
127 multiple metrics related to these factors may lead to higher levels of agreement  
128 between the index and PG&E's net revenues, in large part due to its consideration  
129 of cross-correlation between these three factors. This should lower basis risk and  
130 result in a more effective risk management instrument, particularly as it will bet-  
131 ter account for the financial impacts of compound risks involving the incidence  
132 of both drought and heatwaves, which are often correlated in many parts of the  
133 world [Mukherjee et al., 2020, Zscheischler et al., 2018, Kong et al., 2020]. While  
134 this analysis is applied to PG&E, the new financial instrument could be useful for  
135 any electric utility with concerns over how variability in hydrometeorological  
136 and market conditions will affect its operations and finances.

### 137 **Alternative Regulatory Scenario**

138 Air pollution emissions from power plants impact public health, and these emis-  
139 sions tend to increase when conventional thermal generation is increased to meet  
140 electricity demand, as more expensive sources, which are also often more pollut-  
141 ing, come online. Proposals to limit pollution damages and emissions by using

142 taxes on the pollutants of concern are intended to encourage the adoption of new,  
143 less polluting technologies and have become increasingly common [C2ES, 2022].  
144 If pollution taxes on power plants were imposed in California, it is likely to in-  
145 centivize PG&E to use generators that produce less pollution before dispatching  
146 its higher polluting generators, thereby changing its generation dispatch to lower  
147 emissions and presumably improving public health.

148 Even with the advent of a pollution tax, the utility would still need to dis-  
149 patch its most polluting generators during periods of extraordinarily high elec-  
150 tricity demand, especially if high demand occurs during periods of decreased  
151 hydropower supply (e.g., during drought and/or late summer), as the alternative  
152 would be blackouts (i.e. when demand for electricity exceeds supply) [Nguyen,  
153 2020]. Consequently, during such extreme hydrometeorological conditions, the  
154 pollution tax would impose greater costs on PG&E at times when it is finan-  
155 cially vulnerable, and thus the tax would exacerbate its financial risk. Overall,  
156 the same hydrometeorological conditions that give rise to financial risk also give  
157 rise to increased air pollution [Zeighami et al., 2023]. Therefore, the composite  
158 index-based instrument is also evaluated under a scenario involving a pollution  
159 tax implemented across California to determine the degree to which it can reduce  
160 financial risk in such situations, and thereby remove some of the disincentives for  
161 implementing a tax intended to improve public health. Implementing a financial  
162 instrument to better manage the heightened financial risk that would accompany  
163 the pollution tax on PG&E during periods of extreme hydrometeorology could,

164 therefore, ease the utility's transition to a generation mix that leads to improved  
165 public health.

## 166 **2 Methods**

167 Figure 1 represents the overall modeling framework used in this study. This study  
168 uses the outputs from a unit commitment & economic dispatch model of the  
169 American West (California and West Coast Power Systems model (CAPOW)) run  
170 at an hourly time step using simulated weather and electricity market conditions.  
171 CAPOW's outputs, including generator dispatch and wholesale electricity prices  
172 are used in conjunction with a financial model of PG&E's business operations  
173 to produce estimates of PG&E's annual net revenues. These annual net revenues  
174 serve as targets for financial risk management using multiple strategies. A newly  
175 designed composite index-based contract is then compared against a portfolio of  
176 existing single-index contracts to determine the cost-effectiveness of each ap-  
177 proach in managing PG&E's net revenue variability. The effectiveness of using  
178 the newly designed composite contract is also assessed under an alternative reg-  
179 ulatory scenario, involving a pollution tax designed to reduce public exposure to  
180 pollutant emissions, a scenario in which PG&E's financial risk increases.

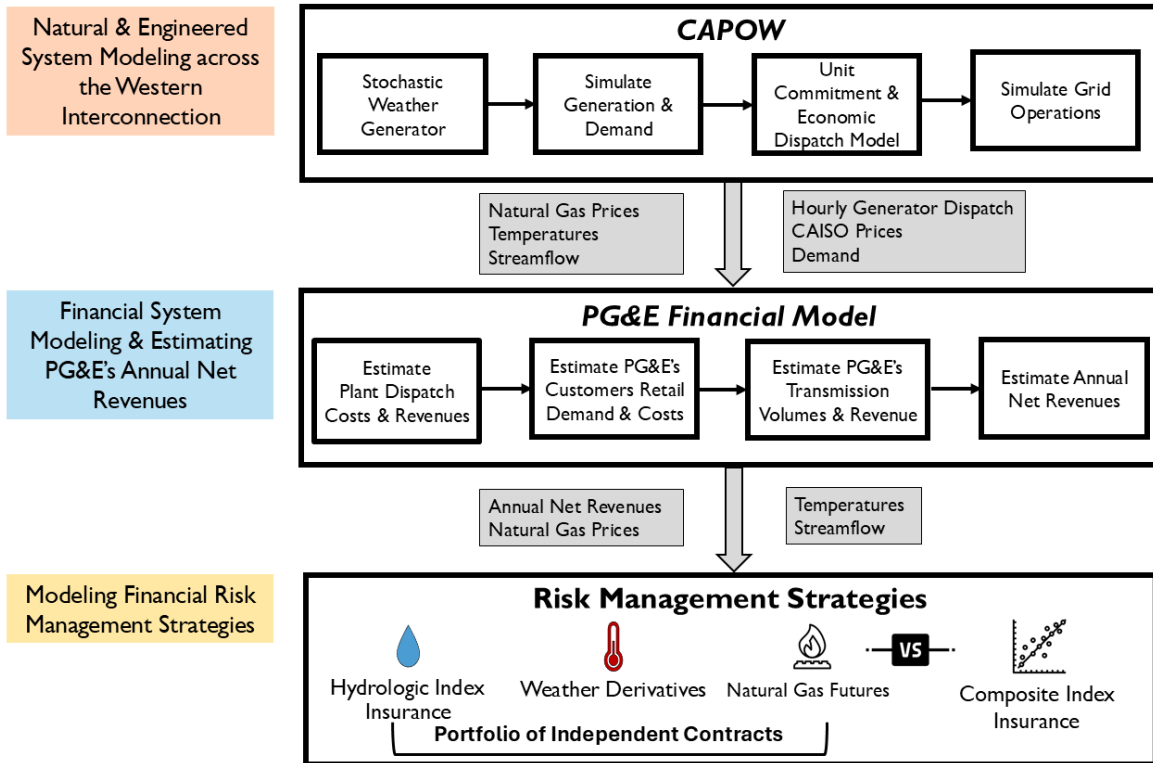

Figure 1: The overall manuscript modeling framework. The only difference between the baseline scenario and the alternative regulatory scenario with a pollution tax is changes in generation costs for thermal power plants, which serve as inputs to the unit commitment and economic dispatch model within CAPOW.

181 **2.1 Study Region**

182 Pacific Gas & Electric provides electricity services for much of northern and cen-  
 183 tral California (Figure 2). Most of PG&E’s business focuses on the generation,  
 184 transmission, and delivery of electricity, and these parts of its business are the  
 185 focus of this analysis. As of 2018-2020, the utility’s primary electricity genera-  
 186 tion sources include nuclear (2,240 MW), conventional hydropower (2,655 MW),  
 187 pumped storage hydropower (1,121 MW), natural gas plants (1,400 MW), solar  
 188 photovoltaic (152 MW), and electricity sourced from third-party electricity gen-

189 erators, primarily renewable (e.g., solar, wind), through power purchase agree-  
190 ments (PPAs) [PG&E Corporation, 2018, 2019, 2020a].

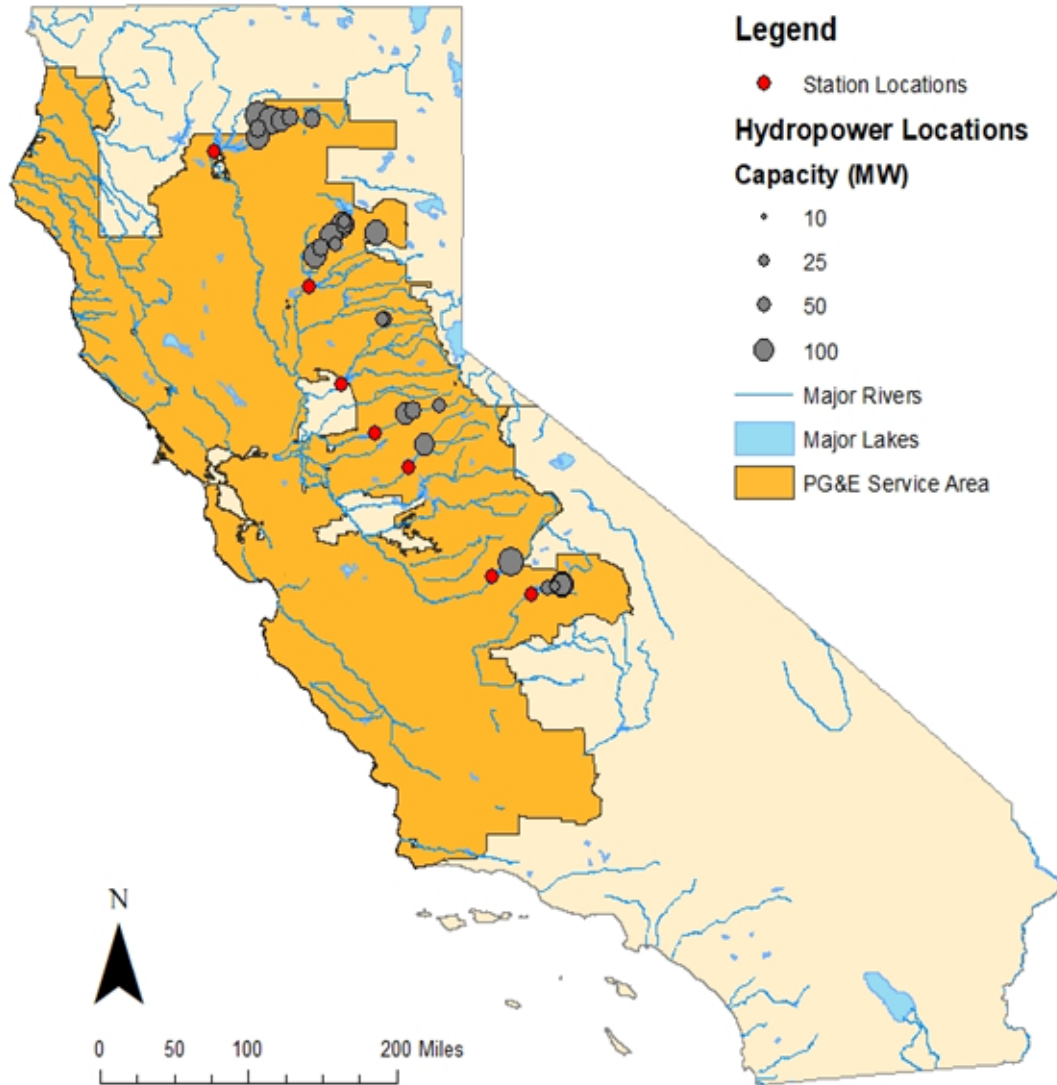

Figure 2: PG&E’s service area in California, showing the locations of its hydropower capacity and the stream-level monitoring stations used in this work [California Energy Commission, 2021, California Natural Resources Agency, 2020, 2022].

191 Some of PG&E’s vulnerability to hydrometeorological risk is due to its hy-  
192 dropower facilities, the majority of which are located at higher elevations in the  
193 Sierra Nevada Mountains [PG&E Corporation, 2022]. A significant portion of

194 the state's precipitation occurs as snow in the Sierra Nevada, which results in  
195 the majority of annual streamflow coming in the spring and summer as snowmelt  
196 [Huning and Margulis, 2017, Serreze et al., 1999]. Variability in snowfall amounts  
197 and timing can negatively affect hydropower operations that have traditionally  
198 relied on snowpack as additional storage for high-altitude reservoirs, most of  
199 which have very limited storage capabilities [Aspen Environmental Group and  
200 M. Cubed, 2005]. In addition to decreasing hydropower generation, drought can  
201 threaten thermal generation through reduced access to cooling water, leading to  
202 a reduction in generation and revenues [van Vliet et al., 2012]. This is primarily  
203 a concern for "once-through" power plants, which use greater amounts of water,  
204 very few of which exist in California [Madden et al., 2013]. Thus, cooling water  
205 issues have not historically been a problem in the state and are not considered a  
206 significant risk to PG&E's operations.

207 Ambient air temperatures are also a key contributor to PG&E's financial risk.  
208 While PG&E generally benefits from periods of warmer weather and increased  
209 electricity demand, short-term temperature extremes caused by heat waves, es-  
210 pecially during late summer when hydropower supply is low, have resulted in  
211 very high market prices for electricity (a problem for PG&E as it buys more elec-  
212 tricity from the market than it sells during these periods) [Nguyen, 2020]. Ad-  
213 ditionally, an altered regulatory environment, including changes to tax policy, is  
214 named in the financial report as a risk that could impact PG&E's financial condi-  
215 tion. This could include the enactment of pollution taxes on air emissions from

216 power plants, which would increase the utility’s costs. As the combination of  
217 drought (less hydropower supply) and heatwaves (increased demand) often force  
218 PG&E to bring its most expensive and dirtiest generation sources online, the tax  
219 would likely be imposed under the same type of hydrometeorological conditions  
220 that already create financial risk.

## 221 **2.2 Modeling Framework**

### 222 **2.2.1 California and West Coast Power Systems Model (CAPOW)**

223 The California and West Coast Power (CAPOW) Systems Model is a Python-  
224 based model that simulates the electrical power system and wholesale electricity  
225 markets across the West Coast region, including all of Washington, Oregon, and  
226 California [Su et al., 2020a]. The model includes the California Independent Sys-  
227 tem Operator (CAISO) wholesale electricity market, in which PG&E participates  
228 in, along with the Mid-Columbia (Mid-C) wholesale electricity market, which  
229 covers most of the Pacific Northwest. It is important to model the entire sys-  
230 tem, as PG&E is influenced by conditions outside its service area. For example,  
231 drought in the Pacific Northwest (Mid-C) reduces hydropower generation and  
232 electricity exports to California, thereby impacting CAISO’s generation mix and  
233 electricity prices.

234 The CAPOW model has two main components: a synthetic weather gener-  
235 ator and a unit commitment and economic dispatch (UC/ED) model that deter-  
236 mines when and how much electricity is generated at each source. Historical

237 West Coast hydrometeorological data, including streamflows and temperatures,  
238 are input to the weather generator, which then uses statistical relationships to  
239 produce daily synthetic hydrometeorological data that are statistically consistent  
240 with historical observations at each monitoring station, while also reproducing  
241 both temporal and spatial autocorrelation in different parameters across loca-  
242 tions throughout the region [Su et al., 2020a]. This stochastic approach allows  
243 for the generation of extreme hydrometeorological events outside of the more  
244 limited historical record, allowing for financial risk management strategies to be  
245 analyzed under a broader range of conditions.

246 The UC/ED model uses the simulated hydrometeorological and grid conditions  
247 (hydropower and thermal generation, electricity demand, renewable availabil-  
248 ity) within a mixed-integer linear optimization to determine generator dispatch  
249 and the wholesale electricity price. This is done by simulating the dynamics of  
250 the CAISO electricity market by determining the generation mix that minimizes  
251 the costs of meeting electricity demand. Generators with the lowest marginal  
252 costs are dispatched first, with more expensive generators dispatched in order  
253 of increasing cost as demand rises. The highest marginal cost generator used to  
254 meet demand sets the market’s wholesale electricity price [US EIA, 2012]. Out-  
255 puts from the UC/ED model include hourly CAISO wholesale electricity prices  
256 (\$/MWh) and hourly generator dispatch for the region. Running the UC/ED  
257 model using historical conditions produces wholesale prices that agree quite well  
258 with observed market prices, with an  $R^2$  value of 0.75 [Su et al., 2020a]. For more

259 details on CAPOW, including its validation and applications, see [Su et al., 2020a,  
260 Kern et al., 2020, Su et al., 2020b]. Variable stochastic natural gas prices are in-  
261 corporated into CAPOW during a post-processing step. This is straightforward  
262 given that gas prices uniformly affect the marginal generation costs of natural  
263 gas plants, which dominate California's electricity generation and are essentially  
264 always the marginal producers that set market prices [Hodge, 2022] (i.e., the or-  
265 der of plant dispatch by the UC/ED is not impacted). For more information on  
266 incorporating variable natural gas prices into the modeled generation costs and  
267 wholesale electricity prices, see Supplementary Materials Note A.

268 Five hundred simulations each of duration one year were generated using the  
269 CAPOW modeling framework. The temporal resolution of each simulation was  
270 hourly leading to 8,760 time-steps. The next step included checks to ensure the  
271 spatial and temporal cross-correlations across the simulations represented the  
272 variability in the data. Across the 500 simulations, a single simulation display-  
273 ing spurious correlations was removed. Given that the framework models the  
274 entire West Coast (Washington, Oregon and California including the entirety of  
275 CAISO), variables of interest for the PG&E domain were extracted. These include  
276 the CAISO hourly market price, demand, streamflow, hydropower generation,  
277 wind and solar power generation, and temperatures across the population cen-  
278 ters within PG&E.

### 279 2.2.2 PG&E Financial Model

280 The generator dispatch schedule and wholesale electricity prices produced by  
281 CAPOW are used as inputs into the PG&E financial model, which describes the  
282 utility's business operations. These consist primarily of the following: (i) gen-  
283 erating electricity via owned and procured assets (i.e., PPAs) to sell on CAISO's  
284 wholesale electricity market, (ii) making purchases from the wholesale electric-  
285 ity market to meet customer demands, and (iii) distributing electricity to con-  
286 sumers. Total electricity generation costs are calculated using the electricity  
287 generated (MWh) by each of PG&E's dispatched plants and the plants' corre-  
288 sponding marginal generation costs (\$/MWh). The PPA contract prices for ac-  
289 quired electricity (\$106.2/MWh for renewable generators and \$33.15/MWh for  
290 conventional thermal generators) are estimated using cost and generation infor-  
291 mation from PG&E's financial report and sustainability report [PG&E Corpora-  
292 tion, 2018, 2020b]. Pacific Gas and Electric sells this generated and procured elec-  
293 tricity on the wholesale electricity market at the current wholesale price and then  
294 purchases electricity back to meet its retail customer demand. Retail customers  
295 are sorted into four general categories: residential, commercial, industrial, and  
296 agricultural. Retail electricity rates used in the model range from \$0.10/kWh to  
297 \$0.22/kWh, depending on both the customer type and time of year, with summer  
298 rates being higher than winter rates [PG&E Corporation, 2018]. Although elec-  
299 tricity consumers in PG&E's service area can choose among different electricity  
300 providers in the region (e.g., through community choice aggregation programs),

301 PG&E still owns much of the existing transmission infrastructure and charges a  
302 fee for any electricity delivered even if PG&E is not the generator.

303 The delivery charge used by the model was estimated using PG&E's publicly  
304 available rate information [PG&E Corporation, 2018]. Model output in the form  
305 of PG&E's revenues (i.e., from retail customers and transmission), its costs (i.e.,  
306 from fuel purchases, PPAs, and net wholesale market purchases), and its hy-  
307 dropower generation are compared against observations of net revenues over  
308 the historical period, which range from \$12 - \$12.3 billion [PG&E Corporation,  
309 2018]. Operations and maintenance (O&M) costs contribute a significant portion  
310 of revenue variability attributed to managing wildfire risk [PG&E Corporation,  
311 2020a]. Since wildfire impacts are not included in this analysis and their impact  
312 cannot be isolated from recent O&M costs and overall additional charges, these  
313 costs are left out of the net revenue calculations. Therefore, it should be noted  
314 that the net revenues analyzed in this study for any given year would likely be  
315 shifted down by O&M costs of a similar magnitude.

316 In order to isolate the influence of hydrometeorological events on PG&E's net  
317 revenues, this work defines annual net revenues (NR) as the following:

$$NR(\$B) = Market_{rev} + Retail_{rev} + Transmission_{rev} - Market_{costs} - Fuel_{costs} - PPA_{costs} \quad (1)$$

318 where,  $Market_{rev}$  are revenues from electricity sold on the wholesale market.

319  $Retail_{rev}$  are revenues from retail customers.  $Transmission_{rev}$  are revenues  
320 from electricity transmission.  $Market_{costs}$  are costs of electricity purchased from  
321 the wholesale market.  $Fuel_{costs}$  are power plant fuel costs.  $PPA_{costs}$  are costs  
322 associated with PPAs. All of these variables are impacted by hydrometeorological  
323 conditions, which in turn affect the supply and demand of electricity.

## 324 **2.3 Managing Financial Risk using Index Based Instruments**

### 325 **Index Insurance Contract Design Considerations**

326 In developing a new index-based financial instrument to manage risk, a primary  
327 objective is identifying an index that can accurately characterize PG&E's finan-  
328 cial risk due to variable hydrometeorology. Daily streamflows at PG&E's major  
329 dams in the Sierra Nevada (which are widespread and thus a useful indicator,  
330 see Figure 2) are used to determine if the region is experiencing a dry year, and  
331 therefore, decreased hydropower generation. The locations of PG&E's major hy-  
332 dropower dams are mapped, and, using the dams' capacities, the percentage of  
333 PG&E's hydropower that corresponds to each streamflow station is identified  
334 (Figure 2). Streamflows at each station are weighted during aggregation to repre-  
335 sent the proportion of corresponding hydropower generating capacity located at  
336 each facility, with the aggregate value representing the hydrologic index. Cooling  
337 degree days (CDD) are used to develop proxy relationships for electricity demand  
338 during the summer as electricity demand is highly correlated with ambient air  
339 temperatures [Hull, 2022, DeVilbiss and Morey, 2021]. These can be aggregated

340 over a specified period (e.g., season, year) to get an understanding of that pe-  
341 riod's electricity demand for cooling and any deviations from expected demand  
342 and revenues that might occur. Using temperatures generated by CAPOW for  
343 major cities (Fresno, Sacramento, San Francisco and San Jose) within PG&E's  
344 service region, annual CDD is computed for each city as:

$$\sum_{i=1}^{365} \max(T_i - 65, 0) \quad (2)$$

345 where,  $T_i$  is the average daily temperature in Fahrenheit. It is assumed that  
346 65 F is the ambient air temperature at which little heating or air conditioning is  
347 needed to maintain a comfortable building temperature with demand for elec-  
348 tricity used for cooling buildings rising linearly at temperatures above that point  
349 [Mathews, 2009]. In order to represent the total regional electricity demand dur-  
350 ing the summer, CDD values are calculated for each city and then aggregated.

351 An important consideration during contract design is whether the contract  
352 buyer or seller has a reasonable ability to predict and/or manipulate the index  
353 and thus the contract outcome. Neither party should have an advantage in terms  
354 of predictive power, such that they have better information regarding the proba-  
355 bility of payouts being made. While predictive power over summer temperatures  
356 and the average annual wholesale electricity price is already limited to very short  
357 periods (e.g., days to weeks), spring and summer streamflows in the Sierra Nevada  
358 Mountains can be predicted using the preceding winter snowfall amounts. Index  
359 contracts based on annual streamflows in this area are, therefore, written before

360 October 1st (beginning of the Water Year) as there is limited snowfall forecasting  
361 ability before this date [Kapnick et al., 2018, Shukla and Lettenmaier, 2011].

362 With respect to streamflow, an ideal index would in many cases use mea-  
363 surements taken upstream of PG&E's dams. In this case, flow data are available  
364 only downstream of the dams, offering the possibility that the utility might be  
365 able to manipulate the hydrologic component of the index. However, the high-  
366 altitude reservoirs that are the source of PG&E's hydropower are relatively small  
367 and have very little interannual storage capability [Aspen Environmental Group  
368 and M. Cubed, 2005], meaning PG&E must effectively allow all the water flowing  
369 into its hydropower reservoirs in a given year to flow out in the same year, ensur-  
370 ing no influence of antecedent storage conditions on the probability of payout.  
371 The contract is thus structured so that the streamflow component of the index  
372 is a function of annual flows thereby reducing concerns over PG&E's ability to  
373 effect the final value. With respect to the use of natural gas prices, there is lit-  
374 tle ability for PG&E to manipulate these as the primary drivers of changes in  
375 these prices are global in nature and independent of drought and temperature  
376 [Su et al., 2020b]. This, along with the use of temperatures at gauges managed by  
377 government agencies, should prevent PG&E from exercising any influence over  
378 any component of the proposed composite index or individual indices.

### 379 **Index Insurance Contract Structure and Pricing**

380 Index-based insurance contracts are typically designed to trigger a payout once  
381 the index drops below, or rises above, a predetermined threshold or a “strike”.  
382 Figure 3 depicts the generalized structure of an index-based insurance contract.  
383 In that case, the strike is set at the 15th percentile of the index (i.e., approximately  
384 15th percentile net revenues), such that payouts are triggered when the index  
385 drops below this level. It is assumed that net revenue losses up to this point are  
386 managed via other means (e.g., reserve fund, lines of credit), with greater losses  
387 considered “unmanaged” if the index contract not in place. This is consistent with  
388 practice, as index-based insurance and other types of risk transfer contracts are  
389 typically used to protect against extreme risks that occur once every 10 years or  
390 less [Meenan et al., 2019]. The selected strike in Figure 3 results in positive net  
391 payouts (years with payouts that are greater than the annual premium) slightly  
392 less than 15% of the time (intersection of the horizontal dotted line with the solid  
393 blue line). Lowering the strike to cover only the most extreme events (e.g., to  
394 the 10th percentile) would result in less frequent net payouts. While the selected  
395 levels of protection provided by the index-based insurance (i.e. one year in 10 or  
396 one year in 5) are roughly consistent with practice, the actual choice of a strike  
397 depends on both the level of financial protection the buyer maintains in other  
398 forms, such as a reserve and/or access to credit, as well as the buyer’s level of  
399 risk aversion.

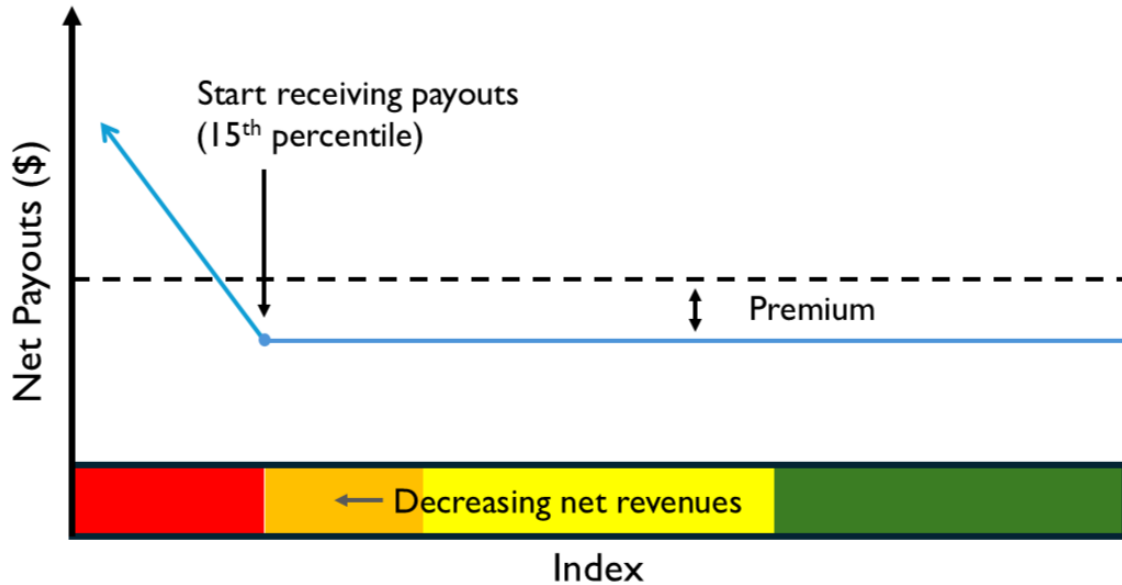

Figure 3: Generalized structure of an index-based insurance contract where the strike is set at the 15th percentile.

400 For a linear payout function, the magnitude of the payout ( $p$ ) is determined by  
 401 the severity of the loss defined by the difference between the strike ( $S$ ) and the  
 402 index ( $I$ ):

$$p(\$B) = m \times \max[S - I, 0] \quad (3)$$

403 where  $m$  is the slope of the payout function (\$ payout per unit of the index).  
 404 If the composite index is already in units of dollars, the payout function can be  
 405 simplified to:

$$p(\$B) = \max[S - I, 0] \quad (4)$$

406 Payouts during years when the composite index falls below the strike are in

407 exchange for an annual premium paid from buyer to seller. The index insurance  
408 contracts in this study are priced using the Braun model [Braun, 2016], a multi-  
409 variate linear econometric model based on reinsurance pricing data from 1997 to  
410 2012, such that:

$$Pre = 221.04 \times EP + 175.08 \times PEAK - 103.58 \times SW + 161.85 \times ROLX \\ -159.76 \times IG + 26.57 \times BBSP$$

411 where, *Pre* is the contract premium relative to the maximum possible payout  
412 (basis points). *EP* is the expected payout in relative to the maximum possible  
413 payout (percentage points). *PEAK* is peak territory designation (1 = yes; 0 =  
414 no). *SW* indicates if the counterparty is well diversified (1 = yes; 0 = no). *ROLX*  
415 is the synthetic rate on line index (reflects reinsurance market cycles) (points).  
416 *IG* indicates if the bond is investment grade (1 = yes; 0 = no). *BBSP* is the  
417 corporate bond spread (percentage points).

418 This pricing method indicates that contracts with higher expected payouts  
419 and maximum possible payouts are more expensive. As many of the factors in the  
420 equation above can be considered consistent across the two scenarios (composite  
421 index and portfolio), a simplified Braun model used in Baum & Characklis (2020)  
422 is applied in this study:

$$Pre = 221.04 \times EP + 304.97 \quad (5)$$

423 Supplementary Materials Note B describes the assumptions made in develop-  
424 ing equation 5. Baum and Characklis [2020] explored this simplified model for  
425 pricing hydrologic-based reinsurance and found that it performed well at recre-  
426 ating observed index-based contract premiums (Pearson correlation of 0.84) de-  
427 scribed in the Artemis database of catastrophe bond and reinsurance contracts  
428 [Artemis, 2018], which seems appropriate as the index insurance contracts con-  
429 sidered here are structurally similar to reinsurance (i.e. risk transfer as opposed  
430 to risk pooling). The simplified Braun model as used in Baum and Characklis  
431 [2020] is used to price the composite index insurance contract and the portfolio  
432 of three independent index insurance contracts based on streamflow, CDD and  
433 natural gas prices.

## 434 **2.4 Composite Index Insurance Contract Design**

435 Index contracts designed to manage an individual risk, such as the financial risk  
436 arising from temperature or electricity price variability, are currently commer-  
437 cially available [Deng and Oren, 2006, CME group]. The Chicago Mercantile  
438 Exchange provides a platform for the exchange of index contracts based on a  
439 variety of weather conditions (commonly known as weather derivatives), such  
440 as temperature, rainfall, and snowfall. Contracts based on deviations from ex-  
441 pected temperatures (e.g., measured as CDDs) are some of the most commonly

442 used weather derivatives [Artemis, 2022]. Using index contracts to manage the  
443 drought risk of hydropower producers is less common, but there are still some  
444 instances of their current use. For example, Uruguay has purchased insurance to  
445 manage variability in precipitation as the country sources 80% of its electricity  
446 from hydropower [The World Bank, 2018]. Together in a portfolio, these exist-  
447 ing types of contracts, based on individual indices, can be combined to manage  
448 PG&E’s financial risk resulting from variable hydrology, temperature, and whole-  
449 sale electricity prices. The objective of this work is to design a composite index  
450 that combines consideration of all three factors including annual streamflows as  
451 a measure of drought, annual CDD as a measure of demand, and average annual  
452 natural gas prices as a measure of market conditions and electricity prices. The  
453 ability of a composite index contract to predict net revenue fluctuations will then  
454 be evaluated relative to a portfolio of single index contracts designed to accom-  
455 plish the same goal.

456 The composite index is constructed by regressing net revenue against the an-  
457 nual streamflow, CDD and natural gas prices over the 500 simulation years. The  
458 predicted value from the regression, given values of the three covariates is the  
459 composite index. 80% of the data were randomly selected for training whereas,  
460 the remaining 20% were used for testing as a means to prevent over-fitting.

$$\text{Net.Revenue}(\$B) \sim \alpha + \beta_1 \times sf + \beta_2 \times CDD + \beta_3 \times NG + \epsilon \quad (6)$$

$$I(\$B) = \alpha + \beta_1 \times sf + \beta_2 \times CDD + \beta_3 \times NG \quad (7)$$

461 where,  $sf$  is the annual streamflow,  $CDD$  is the summer temperature, a proxy  
462 for demand and  $NG$  is the natural gas price. The  $\beta$ 's are the estimated coeffi-  
463 cients and  $\alpha$  is the intercept.  $\epsilon$  are the residuals. The regression parameters are  
464 estimated using 80% of the data selected at random.  $I(\$B)$  is the composite index  
465 and is computed using the estimated coefficients. Given the composite index and  
466 the selected strike level, the Braun method is used to price the composite index  
467 insurance contract.

## 468 **2.5 Portfolio of Individual Contracts Design**

469 To demonstrate the enhanced capability of the composite index-based contract,  
470 a portfolio of three separate single index contracts based on streamflows, CDD,  
471 and average annual wholesale electricity prices is also developed and their risk  
472 management performance is compared against that of the composite index-based  
473 contract described above. Risk management performance is measured as the cost  
474 of achieving the same risk management goal, which in this case is a specified  
475 level of variance reduction in net revenues. The Braun method is used for pricing  
476 all contracts. In order to develop the portfolio, the relationship between each  
477 individual index and net revenues is determined using linear regression (using the  
478 same statistical methods and training-testing split) as the composite index. This is  
479 used to identify the slope of the payout function (\$ per unit of the index) (Equation

480 4) for each contract that will translate the difference between the strike and the  
481 observed index value into a dollar amount, which then becomes a payout that  
482 compensates for net revenue losses. For the portfolio of separate single indices,  
483 the strikes for each index are set such that they individually leads to minimization  
484 of the 95% VaR. Value at Risk (VaR) is used to estimate the maximum potential loss  
485 of an investment portfolio over a specified time period with a given confidence  
486 level, with a 95% VaR in this case indicating that there is a 5% chance that PG&E's  
487 net revenues will be lower than the VaR amount. The overall revenue for the  
488 portfolio of separate indices is computed by accounting for the three different  
489 payouts and premiums, as the revenue plus the payouts minus the premiums. The  
490 strike for the composite index is optimized such that the variance of the hedged  
491 revenues using the composite index is the same as the variance of the hedged  
492 revenues using the portfolio of separate single index contracts. The performance  
493 of the portfolio of single index contracts is then compared to that of the composite  
494 index contract.

## 495 **2.6 Alternative Regulatory Scenario**

496 Zeighami et al. [2023] explored the impacts of pollution taxes on West Coast grid  
497 operations and human health using CAPOW. The pollution taxes were incorpo-  
498 rated into CAPOW by increasing the marginal cost of the power generators that  
499 release emissions of public health concern, namely  $SO_2$ ,  $NO_x$ , and  $PM_{2.5}$ . Each  
500 generator's tax payment is measured in \$/MWh and is individually tailored to

501 reflect the estimated human health damages resulting from its air emissions dur-  
502 ing power generation. The computed damages in Zeighami et al. are used as  
503 the thermal power-plant level pollution estimates in this study. The baseline no-  
504 tax scenario and alternative regulatory scenario use the same stochastic weather  
505 conditions across the 500 simulation year period but with different marginal costs  
506 of generators, which are then passed through CAPOW to simulate grid opera-  
507 tions and through the PG&E financial model to estimate annual revenues. The  
508 effectiveness of the composite index insurance contract in reducing financial risk  
509 is compared against the portfolio of individual contracts for this alternative regu-  
510 latory scenario with a pollution tax. The prevented pollution damages displayed  
511 in Figure S2 are the overall reduction in thermal generation across the no-tax  
512 (baseline scenario) versus the pollution tax scenario, and scaled by the plant level  
513 pollution damages as measured by \$/MWh. The imposition of the pollution tax  
514 results in the highest prevented pollution damages occurring in years with low  
515 streamflows (drought) and hotter summers. Shifting generator dispatch to less  
516 polluting generators during hot and dry years has the significant potential to im-  
517 prove public health, but the enactment of pollution taxes also has the potential  
518 to introduce greater financial risk for PG&E.

### 519 **3 Results**

520 The first sub-section of the results includes assessment of the CAPOW and PG&E  
521 financial model by comparing simulation metrics against the publicly available

522 metrics provided by PG&E. It is then followed by testing the efficacy of the com-  
523 posite index insurance contract using simulated hydrometeorological and market  
524 conditions produced by CAPOW in reducing risk in the unmanaged net revenues  
525 generated by the PG&E financial model. The composite index's performance and  
526 cost effectiveness are then compared to that of a portfolio of individual contracts  
527 based on the same indices that constitute the composite index. Both the compos-  
528 ite index contract and the portfolio of individual contracts are assessed on the  
529 basis of their effectiveness in reducing the minimum net revenues, 95% VaR, and  
530 costs of risk mitigation. The composite index contract is then tested with altered  
531 system dynamics that is modeled as a response to air pollution taxes on power  
532 plants, a scenario that changes PG&E's financial risk. The latter scenario offers an  
533 additional opportunity to test the effectiveness of the composite index contract  
534 in limiting the exacerbated tail end financial risks associated with the imposition  
535 of the pollution tax and thus reduce one disincentive associated with an action  
536 intended to improve public health.

### 537 **3.1 PG&E Financial Model Assessment**

538 This section includes assessment and evaluation of the outputs from CAPOW and  
539 PG&E financial model against PG&E's publicly available financial metrics. The  
540 combined CAPOW and financial model generate outputs and simulations that  
541 agree well with observed values (Figure 4). Figure 4 (A) displays the distribution  
542 of the total deliveries in GWh across the generated simulations with the overall

543 spread being from 80,000 - 85,000 GWh. The three red dots denote the deliveries  
 544 by PG&E in the years 2016, 2017 and 2018. The extent of the annual energy  
 545 deliveries in simulations covers the three years, but has a bias with respect to  
 546 future potential years with lower energy deliveries.

547 Furthermore, the model accurately models the split in the revenue across  
 548 the residential, commercial, industrial and agricultural sector. The mean across  
 549 these sectors in the generated simulations are 41%, 39%, 11% and 9% respectively.  
 550 The mean of the recorded fraction sectoral revenue during 2016-2018 was 41%,  
 551 40%, 12% and 8% respectively suggesting that the PG&E financial model captures  
 552 the overall sectoral distribution within the utility.

Figure 4: Comparison of CAPOW and Financial Model Results with observed values. (A) - Histogram of Annual Energy Deliveries (in GWh) by PG&E across the generated simulations. The three red dots correspond to the actual PG&E energy deliveries in 2016-2018. (B) - Histogram of PG&E's Annual Net Revenues (in \$ billion) across the generated simulations. The three red dots correspond to the actual PG&E net revenues in 2016-2018.

553 The histogram in Figure 4 (B) displays the spread in net revenues generated by  
 554 the financial model, with the red dots denoting the revenues in the years 2016,

555 2017 and 2018. The net revenue is an important parameter which determines  
556 the overall financial health of the utility, and the generated simulations appear  
557 to represent the spread in the distribution across the selected years reasonably  
558 well.

### 559 **3.2 Influence of Market & Hydrometeorological Conditions**

560 The financial risk posed to PG&E by variability in annual streamflow, summer  
561 temperatures, and natural gas prices is depicted in Figure S3 and Figure 5. The  
562 net revenues across the simulations exhibit considerable variability ranging from  
563 11.5-13 \$ billion, and a mean of 12.2 \$ billion. In this study, dry years are de-  
564 fined as annual streamflow below the 25th percentile, which reflects the U.S.  
565 Geological Survey’s classification of “below normal” year [USGS, 2022]. Fig-  
566 ure S3 (B) demonstrates that PG&E’s mean net revenues typically suffer, albeit  
567 marginally, during years with low streamflows, which result in a decrease in  
568 hydropower generation and increased reliance on more expensive thermal gen-  
569 eration. Simulation years with cool summers (defined as annual CDD below the  
570 25th percentile) also result in lower mean net revenues (Figure S3 (C)). This is  
571 a consequence of a large fraction PG&E’s revenue coming from selling power  
572 (for cooling and air-conditioning) to its residential customers that have higher  
573 rates in the summer due to seasonal pricing. Cooler summers reduce electricity  
574 demand, thereby reducing revenues. High natural gas prices (defined as prices  
575 above the 75th percentile across the simulations) lead to the largest reductions in

576 net revenue (Figure S3 (D)). Natural Gas fired power plants are almost always the  
577 marginal generator within CAISO dictating the overall price per MWh, and at the  
578 annual time scale wholesale electricity prices are highly correlated with natural  
579 gas prices (Pearson correlation of 0.98 (Figure S4)). Consequently, higher prices  
580 of natural gas result in higher costs of energy procurement for PG&E, decreasing  
581 revenues since PG&E buys more power from CAISO than it sells into it.

582 Figure 5 displays the compound risk to net revenues due to the influence of  
583 natural gas prices, CDD and streamflow across the generated simulations. The  
584 dotted line denotes the 20th percentile of the simulated revenues. The strongest  
585 determinant of net revenue is the natural gas price, with higher natural gas prices  
586 associated with lower net revenues. The effect of CDD on net revenues is dis-  
587 played using the color scheme and is less pronounced, but crucial. Net revenues  
588 are greater in years with higher CDD, which is attributed to the fact that total  
589 demand is highly correlated with CDD (Pearson correlation of 0.9).

590 The highlighted datapoints A, B and C in Figure 5, identify the years with  
591 the three highest CDD values respectively. Point A is the most profitable for  
592 the utility with the highest net revenues given that this year corresponds with  
593 low natural gas prices and high summer temperatures enabling the utility to buy  
594 power cheaply and sell larger quantities of it to its customers. The profitability  
595 changes a bit as we move to point B where the demand still exists due to high  
596 CDD, but the cost of generation goes up due to high natural gas prices, thereby  
597 reducing net revenue. Point C, D and E, refer to the years with the three highest

598 market prices. Given the strong relationship between prices and net revenues  
599 points E and D represent the two lowest net revenues years. Point C represents a  
600 somewhat anomalous situation as it is a year with the third highest CDD, which  
601 would suggest high demand and net revenues, but natural gas prices are also  
602 high and this more than compensates and lowers net revenues. An additional  
603 confounding factor in the year represented by point C is that it corresponds to a  
604 low streamflow year thereby further reducing PG&E's generation and increasing  
605 costs, given that PG&E buys more power from CAISO than it sells into it. This  
606 situation highlights the double-edged sword of demand, as described by a year  
607 in which PG&E is forced to buy power at high costs to satisfy higher demand,  
608 thereby reducing its net revenues.

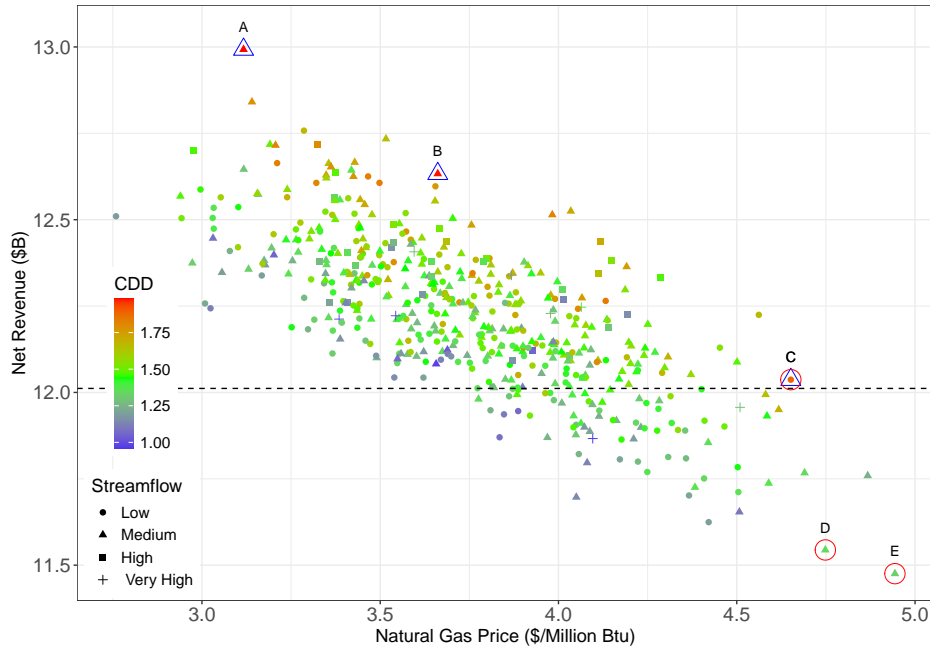

Figure 5: Compound Influence of Market & Hydrometeorological Conditions. Net revenues versus natural gas prices across the simulations. Each point refers to an individual year. The color scheme depicts the CDD and the symbol shape denotes the streamflow across the simulations, with warmer colors denoting warmer summers (with higher electricity demand). The dotted line denotes the 20th percentile of the simulated revenues.

### 609 3.3 Composite Index

610 The multiple interactions between the market and hydrometeorological conditions  
 611 motivates the development of the composite index, which captures the joint cor-  
 612 relation with net revenues. The composite index is constructed by regressing net  
 613 revenue against the annual streamflow, CDD and natural gas prices, and is the  
 614 predicted value of the regression, given values of the three covariates. Eighty  
 615 percent of the data were randomly selected for training whereas, the remaining  
 616 twenty percent were used for testing. The results from the regression on the  
 617 training dataset are displayed in Table S1. The model testing error and training

618 error were comparable indicating no presence of overfitting (Figure S5). Overall,  
619 the composite index (I) is computed as follows:-

$$I(\$B) = 0.074 \times sf + 0.108 \times CDD - 0.161 \times NG + 12.227 \quad (8)$$

620 where,  $sf$  is the annual streamflow,  $CDD$  is the cooling degree days (a mea-  
621 sure of summer temperature) and  $NG$  is the annual mean natural gas price. All  
622 three covariates were standardized, transforming them to a mean of zero and  
623 standard deviation of one. The predicted index values were calculated using the  
624 deterministic component of the regression equation, omitting the stochastic er-  
625 ror term to ensure contractual transparency and computational certainty in the  
626 insurance settlement process.

627 Figure 6 displays the correlation matrix across the variables used to construct  
628 the portfolio of instruments (streamflow, CDD and Natural Gas), as well as how  
629 each correlates with net revenues and the composite index. The Pearson corre-  
630 lation value for each variable pair is denoted within the sub-plot along with the  
631 linear fit estimated from the entire set of simulations. Streamflow and CDD are  
632 negatively correlated with a coefficient of -0.26 (p=2.1e-09), a relation between  
633 dry years and hot summers. Natural gas price does not vary (near zero corre-  
634 lation) with streamflow and CDD largely because natural gas prices are largely  
635 set by national and global markets, such that variability in demands in California  
636 alone do not have much of an impact.

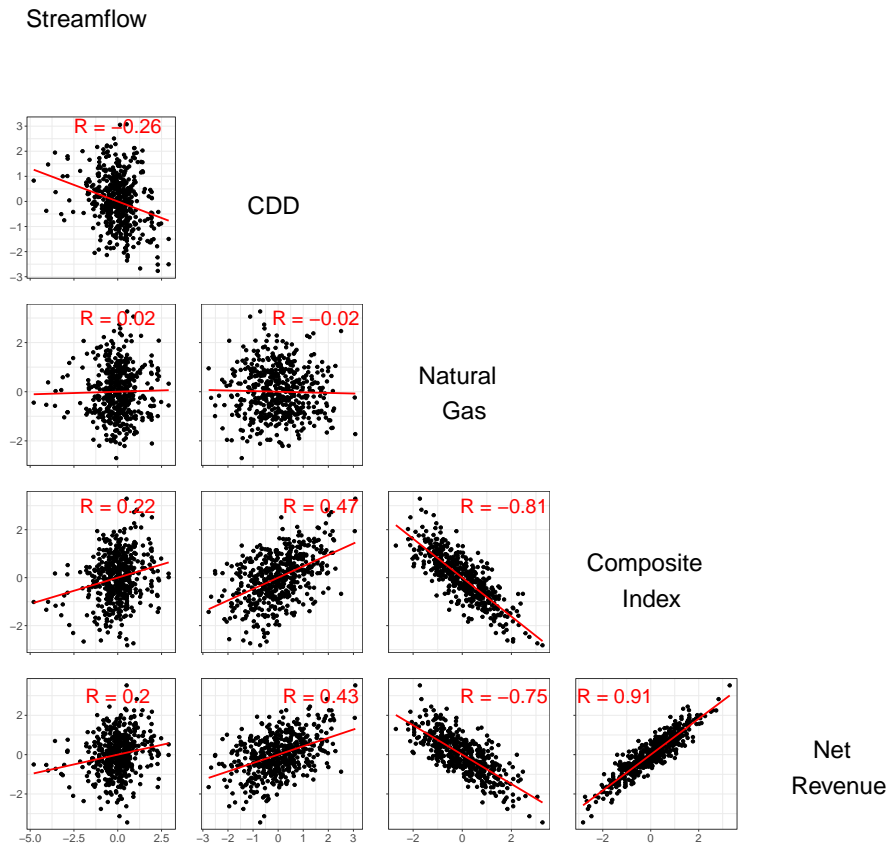

Figure 6: Correlation matrix of annual streamflow, CDD, natural gas prices, the composite index, and net revenues. All values are standardized. The Pearson correlation coefficients for each variable pair are denoted in red within the sub-plot.

637 Streamflow and net revenue are weakly positively correlated ( $R=0.20$ ,  $p = 7.4e-$   
638  $06$ ), indicating that low streamflow years contribute to lowering net revenues.  
639 Net revenues and CDD, have a stronger positive correlation ( $R=0.43$ ,  $p < 2.2e-16$ ),  
640 indicating that net revenues improve with increasing summer temperatures. Net  
641 revenues are negatively correlated with natural gas prices ( $R=-0.75$ ,  $p < 2.2e-16$ ),  
642 displaying the effect of high natural gas prices in reducing the overall net rev-  
643 enues. Each of these three variables are used as individual risk transfer instru-

644 ments within the portfolio of available instruments, and are compared against  
645 the composite index based instrument.

646 While these individual relationships capture one-to-one correlations between  
647 each variable and net revenue, the composite index (eqn. 8) is much more highly  
648 correlated with net revenues (Pearson correlation of 0.91,  $p < 2.2e-16$ ) than any  
649 of the individual components. The composite index captures these relationships  
650 in a way that indices based on each individual component do not, accounting  
651 for interactions between components (e.g. the joint probability of drought and  
652 heatwave) that amplify or reduce net revenue losses relative to what is observed  
653 when only considering the effects of each component individually. In this way,  
654 a contract based on the composite index decreases basis risk relative to what is  
655 observed when considering the effects of each component individually, reducing  
656 the incidence of over/under-payment and leading to a more effective financial  
657 instrument. While this finding was foreshadowed in previous research, it has  
658 not been tested or quantified.

### 659 **3.4 Composite Index Contract Performance**

660 A 100-year time series (subset of simulated years) illustrates the performance of  
661 the composite index contract (Figure S6) and demonstrates that it is effective in  
662 raising the net revenue floor (i.e., the lowest net revenues) experienced by the  
663 utility over the period in question. A similar plot displaying the effectiveness of  
664 the composite index contract across all the simulation years is attached in the

665 supplement (Figure S7). The mean net revenues over this period decreases due to  
666 the annual contract premium, but payouts are reliably triggered during the worst  
667 performing years, limiting the utility's losses during adverse conditions.

668 The composite index contract improves the revenue floor (worst-case net rev-  
669 enues) from \$11.47 billion to \$11.76 billion (an improvement of almost \$300 mil-  
670 lion) and raises the 5th percentile risk threshold from \$11.87 billion to \$11.91  
671 billion (an improvement of \$45 million) in exchange for an annual premium of  
672 \$47.5 million that lowers PG&E's mean net revenue accordingly. The portfolio of  
673 single index contracts is also designed to limit low net revenue years and repro-  
674 duce the same overall variability in net revenues (measured in terms of variance)  
675 as the composite index contract. However, it does not perform as well as the  
676 composite index contract in limiting the net revenue floor experienced, and it  
677 costs significantly more (Table 1), largely as a result of basis risk. The composite  
678 index contract reduces the variance of PG&E's net revenues to a level of 37,100  
679 ( $\$M^2$ ) at a premium cost of \$45.7 million annually, which is significantly less ex-  
680 pensive than the cost of a portfolio of individual contracts (\$82.5 million) that  
681 produces the same net revenue variability. The greater aggregate premium cost  
682 of the portfolio results from its higher basis risk, which leads to overpayments  
683 during years without substantial losses and a higher expected aggregate payout.  
684 The higher aggregate payout is a function of the lower correlation between utility  
685 losses and payouts, thus more payouts are required to achieve the same risk re-  
686 duction as that reached via the composite index contract. The selected strike for

687 the composite index is near the 15th percentile, refer Table S2 for the influence  
 688 of the strike on risk management.

Table 1: Performance of the composite index contract and the portfolio of individual contracts compared to unmanaged net revenues.

	Unmanaged Net Revenues	Net Revenues Managed with Composite Index	Net Revenues Managed with Portfolio
Premium (\$M)	–	45.5	81.3
Expected Payout (\$M)	–	15.7	27.3
Loading (\$M)	–	29.8	54
Mean Net Revenue (\$M)	12,226	12,196	12,172
Net Revenue Variance (\$M) <sup>2</sup>	47,280	37,090	37,100
Net Revenue 5 <sup>th</sup> Percentile (\$M)	11,871	11,915	11,870
Minimum Net Revenue (\$M)	11,475	11,764	11,656

689 Further evidence of basis risk is seen in histograms comparing PG&E’s un-  
 690 managed losses with the payouts from both the composite index contract and the  
 691 portfolio (Figure 7). In this case, the “portfolio payout” is the aggregate payout  
 692 calculated by summing the payouts from the individual contracts in the portfolio.  
 693 The areas of the payout distribution that do not overlap with the distribution of  
 694 unmanaged losses represent over/under-payments. Comparatively, the compos-  
 695 ite index contract does not produce many instances of overpayments. There is  
 696 still some level of basis risk with the composite index contract, and this some-  
 697 times leads to small underpayments during years when PG&E has accrued un-  
 698 managed losses, but these are relatively minor and occur less frequently than the  
 699 portfolio strategy’s overpayments.

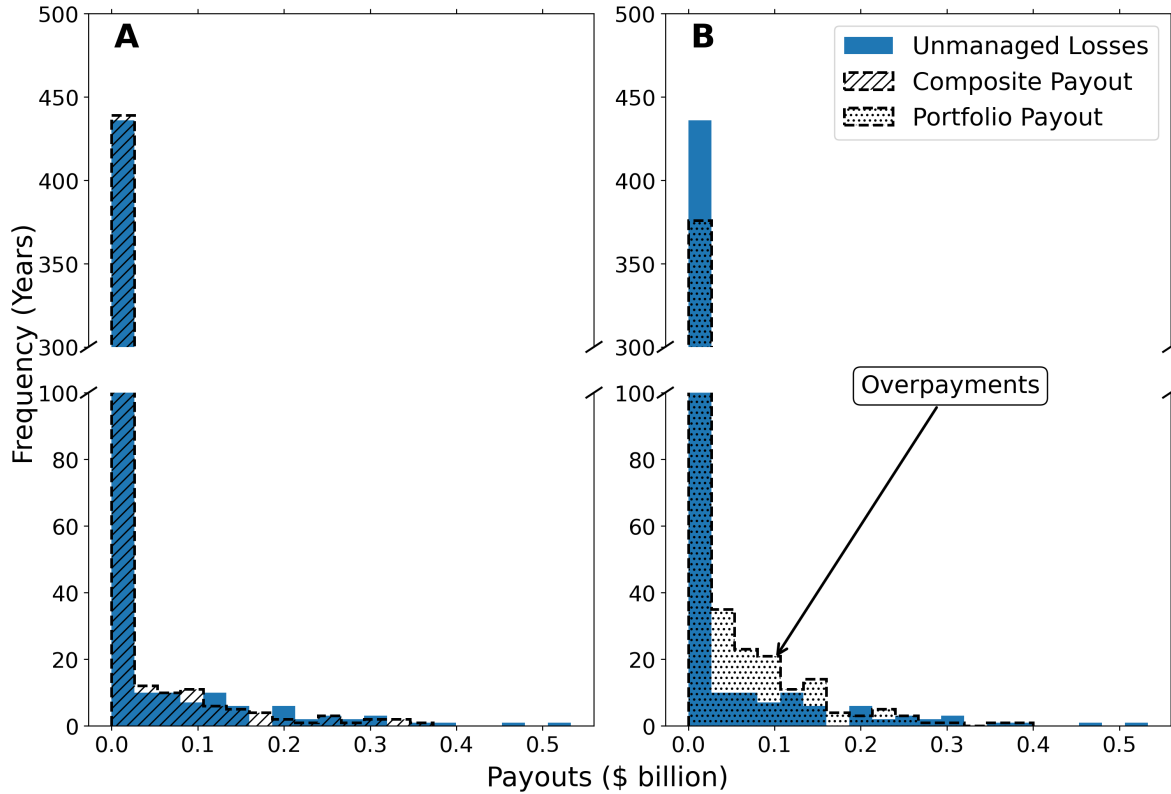

Figure 7: PG&E’s simulated unmanaged losses and payouts from (A) composite index insurance and (B) a portfolio of contracts based on the same indices as the composite index. The “portfolio payout” is the aggregate payout calculated by summing the payouts from the individual contracts in the portfolio.

700 A short illustrative time series of payouts (sub-set across of simulated years)  
 701 from both the composite index contract and the three individual contracts in the  
 702 portfolio shows the individual index contracts are frequently triggered during  
 703 years without unmanaged losses (i.e., unmanaged net revenues below the 15th  
 704 percentile) (Figure 8). Meanwhile, the composite index contract is reliably trig-  
 705 gered during the worst net revenue years, and the magnitude of payouts from  
 706 the composite contract better correlates with the unmanaged losses than those  
 707 from the individual contracts.

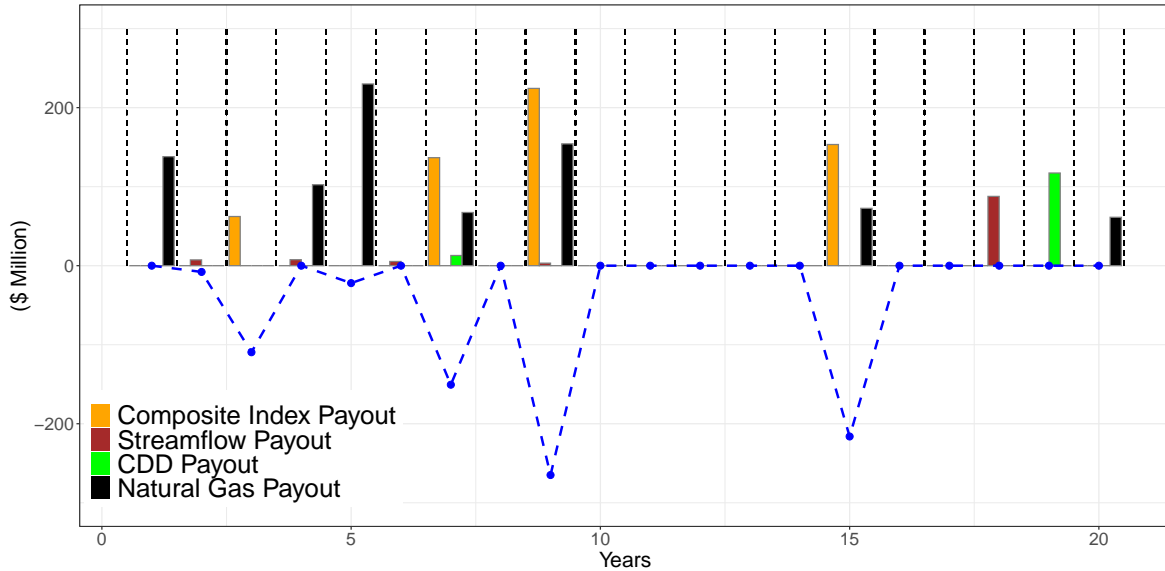

Figure 8: Time series subset of the payouts from the composite index insurance and the payouts from the portfolio of contracts against the unmanaged losses (blue dotted line) experienced by PG&E during those years.

### 708 3.5 Application to an Alternative Future Scenario

709 The simulations from CAPOW and the PG&E financial model allow for the finan-  
 710 cial implications of pollution taxes for PG&E to be explored and the effectiveness  
 711 of the composite index contract to be tested under this alternative regulatory  
 712 scenario.

#### 713 Overall Changes in Net Revenue

714 Annual net revenues across the tax and no tax scenarios are shown in Figure S8.  
 715 The pollution tax reduces PG&E's annual mean net revenues, but also increases  
 716 the financial risk of very low net revenues (i.e. greater tail risk). While the mean  
 717 net revenues decrease by \$ 327 million, the minimum net revenue reduces by \$

718 369 million due to the pollution tax, whereas the 95% VaR value decreases by 360  
719 million USD.

#### 720 **Constructing the new Composite Index**

721 Pollution taxes alter how PG&E is financially impacted by hydrometeorological  
722 extremes. In the baseline generation scenario with no pollution taxes, the util-  
723 ity financially benefits from summers with high temperatures as this increases  
724 demand for electricity and PG&E's revenues from electricity sales (Figures 6).  
725 However, with the pollution tax implemented, the correlation between higher  
726 temperatures and the resulting net revenues is reduced (Pearson correlation of  
727 0.3 ( $p=1.4e-11$ ) instead of the earlier 0.43) as PG&E brings more polluting power  
728 plants online during periods of high demand and the pollution tax increases  
729 PG&E's costs (Figure S9). On the other hand, the relationship between stream-  
730 flow and net revenues becomes stronger, with lower streamflow years associ-  
731 ated with lower revenues in this regulatory scenario (Pearson correlation of 0.28  
732 ( $p=9.1e-11$ ) instead of the earlier 0.19) (Figure S9). Furthermore, average annual  
733 wholesale electricity prices are higher with pollution taxes, and these prices now  
734 have stronger correlations with streamflow and CDD when compared to the no-  
735 tax scenario. This increased correlation relative to the baseline scenario is in part  
736 due to the pollution taxes, which drive up wholesale electricity prices during  
737 periods of high demand and loss of hydropower forces the utility to run more  
738 polluting plants and incur higher tax payments.

739 The composite index insurance contract accounts for these shifted relation-  
740 ships and enables the utility to reduce its losses. By limiting the losses PG&E  
741 would experience as a result of the pollution tax, the organization should be able  
742 to more easily manage the implementation of the tax thereby reducing at least  
743 some of potential arguments it. The composite index is constructed using the  
744 same methodology as in the no tax scenario. Refer to Supplement Note D for fur-  
745 ther details. The composite index ( $I$ ) is slightly modified in this altered scenario  
746 to reflect the effects of the shifted relationships with demand:

$$I(\$B) = 0.094 \times sf + 0.091 \times CDD - 0.18 \times NG + 11.9 \quad (9)$$

747 where,  $sf$  is the annual streamflow,  $CDD$  is the cooling degree days (a mea-  
748 sure of summer temperatures), and  $NG$  is the annual mean natural gas price.  
749 All three covariates were standardized, transforming them to a mean of zero and  
750 standard deviation of one. The adjusted composite index again correlates very  
751 well with PG&E's net revenues ( $R^2$  of 0.91 (Figure S9)), and a contract based on  
752 this modified index is designed using a strike at the 18th percentile that, similar  
753 to the baseline contract, corresponds to payouts being triggered roughly one in  
754 six years.

### 755 **Effectiveness of Composite Index**

756 The composite index contract improves the worst-case net revenues in a pollu-  
757 tion tax scenario from \$11.1 billion to \$11.4 billion (an improvement of over \$300

758 million) and raises the 5th percentile risk threshold from \$11.51 billion to \$11.57  
759 billion (an improvement of \$64 million) in exchange for an annual premium of  
760 \$63 million that lowers PG&E's mean net revenue accordingly. Under this al-  
761 tered regulatory scenario, PG&E's net revenues are lower during years when the  
762 prevented pollution damages are lower, given that high natural gas prices lower  
763 net revenues and incentivize the use of dirtier alternative source thermal plants.  
764 Nonetheless even in these years, where the pollution tax reduces PG&E's rev-  
765 enues, the composite index contract helps increase the revenue floor. The use of  
766 this composite index contract therefore seems capable of significantly reducing  
767 the increased financial risk that would accompany the implementation of a pollu-  
768 tion tax, especially during years with extremely unfavourable hydrometeorology.  
769 The composite index contract also significantly reduces overall net revenue vari-  
770 ability, decreasing the coefficient of variation in net revenues from 0.02 to 0.017  
771 (56500 ( $\$M^2$ ) to 42040 ( $\$M^2$ )). For comparison, the composite index contract  
772 implemented under the first scenario without pollution taxes results in a smaller  
773 reduction in the coefficient of variation from 0.018 to 0.016 (47300 ( $\$M^2$ ) to 37100  
774 ( $\$M^2$ )). Thus, the composite index contract is even more effective at reducing fi-  
775 nancial risk in a scenario involving pollution taxes than it is in a scenario with  
776 no pollution taxes.

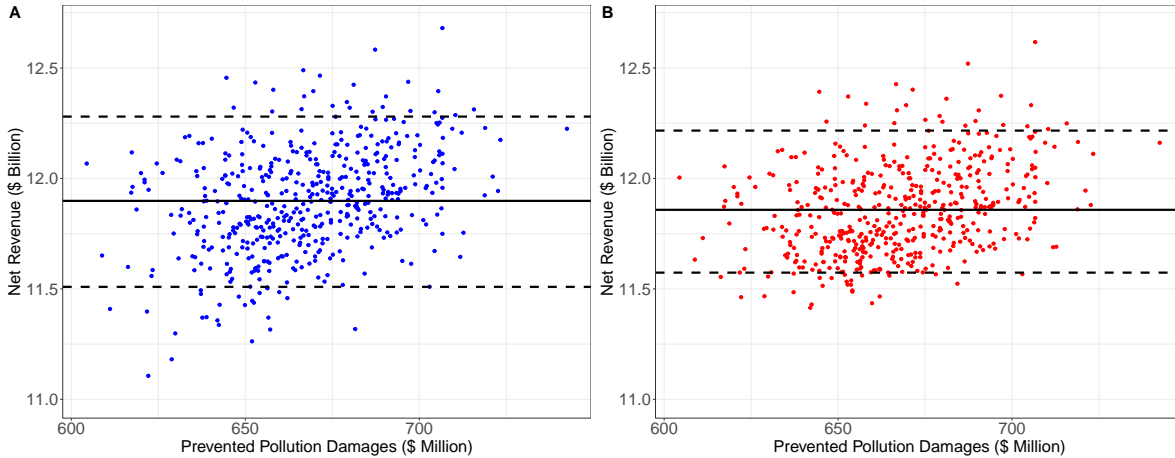

Figure 9: Effectiveness of the composite index during the pollution tax scenario. (A) Unmanaged net revenues and (B) net revenues managed using a composite index contract versus the prevented pollution damages within the California. For both sub-plots the solid black line denotes the mean, whereas the dotted black lines denote the 5th and 95th percentile of the net revenues.

## 777 4 Discussion

778 These results suggest that financial contracts based on a composite index can  
 779 more cost-effectively manage the financial risk imposed on electric utilities as a  
 780 result of extreme hydrometeorological conditions and the higher electricity mar-  
 781 ket prices that accompany them. A financial risk management strategy based  
 782 on a composite index contract outperformed a portfolio of single index contracts  
 783 with the same constituent indices by achieving the same variance in net rev-  
 784 enues for roughly half the price, largely due to the lower basis risk associated  
 785 with the composite index contract. This is driven by the higher correlation be-  
 786 tween PG&E's net revenues and the composite index, a result of the composite  
 787 index incorporating the compound effect of all three index components, which  
 788 can amplify or diminish net revenue losses due to correlations between factors

789 such as droughts and heatwaves. Vertically integrated utilities with diversified  
790 generation mixes, especially those that include a large fraction of renewables  
791 whose generation is highly influenced by hydrometeorological conditions, could  
792 benefit most from composite index contracts, as environmental factors have a  
793 larger influence on their overall generation mix, a situation likely to impact more  
794 utilities in the future. A primary benefit of the improved risk management strate-  
795 gies that result could be a better credit rating and lower interest rates, reducing  
796 overall utility borrowing rates, which should eventually lead to lower consumer  
797 prices. With respect to steps needed to develop a commercially viable product,  
798 the composite index would need to be modified to account for model error, as  
799 CAPOW tends to overestimate the impacts of some hydrometeorological condi-  
800 tions due to assumptions made in the model (e.g., simplified transmission infras-  
801 tructure topology). In addition, this work uses stationary hydrometeorological  
802 conditions, meaning contract premiums may need to be revised to account for  
803 climate change impacts on the frequency and magnitude of extreme hydromete-  
804 orological events.

805 The coincidence of extremely hot and dry periods, posing a threat to both  
806 the financial stability of the utility and the public health of nearby communities  
807 through the increased use of more heavily polluting thermal generation is also  
808 an area that should draw continued interest. While a pollution tax on the result-  
809 ing higher emissions can reduce pollution damages, it is also likely to increase a  
810 utility's financial risk. Under a scenario with a pollution tax, hot and dry periods

811 generally decrease net revenues as the utility is forced to dispatch its most pol-  
812 luting and thus most highly taxed, power plants in order to meet demand. The  
813 composite index contract shows promise in terms of effectively reducing the in-  
814 creased financial risk driven by a pollution tax. Applying the composite index  
815 contract to a scenario that includes a pollution tax suggests that the contract can  
816 be used to facilitate improved public health by removing disincentives for actions  
817 like a pollution tax that may lead to greater financial risk.

818 Further research might include explore different types of contract structures  
819 and risk management strategies for managing net revenue variability at shorter  
820 timescales (e.g., during blackouts). A composite index contract developed for use  
821 during conditions at shorter timescales could offer similar advantages, though  
822 the types of risks being addressed might change (e.g., at shorter timescales, heat  
823 waves pose more of a financial risk than at an annual timescale). Contracts with  
824 shorter durations would be especially useful in a pollution tax scenario, as pollu-  
825 tion taxes can fail to reduce pollution damages during extremely hot days in late  
826 summer when hydropower is simultaneously low, and all available generation  
827 sources must be dispatched to avoid blackouts as described by Zeighami et al.  
828 [2023].

## 829 **5 Conclusion**

830 Variability in hydrometeorological conditions poses a significant financial risk  
831 to electric utilities, a risk that arises from intermittent fluctuations in electricity

832 supply and demand that drive unpredictable swings in costs and revenues. A  
833 composite index insurance contract tailored to manage these hydrometeorologi-  
834 cal risks is just as effective as, and significantly less expensive than a portfolio of  
835 separate contracts currently commercially available. Taking effective steps to sta-  
836 bilize net revenues with financial instruments can help satisfy investors, lenders,  
837 and others (e.g., credit rating agencies) that a utility's financial risk is being better  
838 managed, contributing to both improved long-term financial stability and lower  
839 costs. These findings may have broad applicability as investor-owned electric  
840 utilities accounted for 34.7% of total electricity generation in the United States  
841 as of 2022 [Edison Electric Institute, 2023]. Concerns over climate change have  
842 resulted in electric utilities coming under increasing scrutiny regarding their fi-  
843 nancial exposure to hydrometeorological risks, making new tools and strategies  
844 for managing these risks increasingly important.

#### 845 **Data and Code Availability**

846 The code needed to replicate the analysis can be found at <https://github.com/yashamonkar/CompositeIndexInsurance>. The underlying method-  
847 ology used to generate the simulations follows Zeighami et al. [2023]. The entire  
848 data along with the underlying simulations and the code used in this study is  
849 made publicly available at <https://zenodo.org/records/14933915>.

## 1151 **Supplementary Materials**

### 1152 **Note A: Post-Processing of Variable Natural Gas Prices**

1153 Variable natural gas prices are generated by the Ornstein-Uhlenbeck mean re-  
1154 verting model (Uhlenbeck & Ornstein, 1930) based on historical California natu-  
1155 ral gas prices. In order to factor variable natural gas prices into marginal gener-  
1156 ation costs (\$/MWh), the average heat rates (MMBtu/MWh), a measure of a gen-  
1157 erator's efficiency, of PG&E's natural gas plants are multiplied by the simulated  
1158 natural gas prices (\$/MMBtu). Variable natural gas prices are incorporated into  
1159 wholesale electricity prices by first determining which type of generator is set-  
1160 ting the price (e.g., solar, wind, natural gas, etc.). If it's determined to be a natural  
1161 gas generator, the wholesale electricity price (\$/MWh) under constant natural gas  
1162 prices is divided by the constant natural gas price (\$/MMBtu) used by CAPOW to  
1163 determine the generator's approximate marginal heat rate (MMBtu/MWh). The  
1164 marginal heat rate is then multiplied by the variable natural gas price to deter-  
1165 mine the "new" wholesale electricity price under natural gas price variability.

### 1166 **Note B: Braun Premium**

1167 In order to price the index contracts using the Braun premium (Braun, 2016), the  
1168 following simplifying assumptions are made. Peak territory is a binary variable  
1169 (1 = yes; 0 = no) that represents if the contract is based in the United States. Since  
1170 a majority of catastrophe risk capital is based in the United States, reinsurance

1171 based on U.S. risk does not contribute to geographically diversifying the coun-  
1172 terparty's risk portfolio. PEAK is set to 1 for pricing the index contracts as the  
1173 financial risks they manage are based in the United States. The binary variable  
1174 SW (1 = yes; 0 = no) represents if the counterparty is well diversified, which  
1175 can lower the premium. It is assumed that the counterparty of the index con-  
1176 tracts will be well diversified, so this variable is set to 1. The rate on line index  
1177 variable, ROLX, is a synthetic index that reflects changes in reinsurance market  
1178 cycles. Baum & Characklis (2020) used the historical ROLX average over the pe-  
1179 riod 1997-2012, and this value is similarly used in this work. The binary variable  
1180 IG (1 = yes; 0 = no) signifies if the bond is investment grade, and this value is  
1181 set to 0, since the majority of catastrophe bonds are noninvestment grade. The  
1182 BBSPR variable is set to 3.5%, representing the historical average BB corporate  
1183 bond spread relative to the spot Treasury curve over the last 20 years.

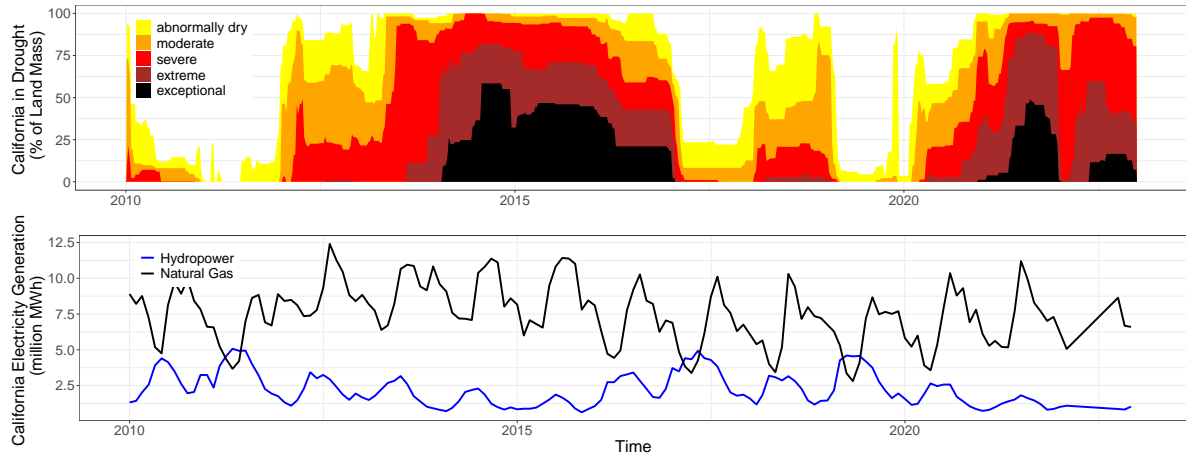

Figure S1: The historical relationship between drought (top) and California’s natural gas and hydropower generation (bottom) from 2010-2022 [National Drought Mitigation Center, 2023, U.S. EIA, 2024].

Figure S2: Prevented pollution damages (i.e. improved public health outcomes) across California versus annual streamflow within the PG&E operating domain with warmer colors representing higher annual CDD (i.e., higher summer temperatures).

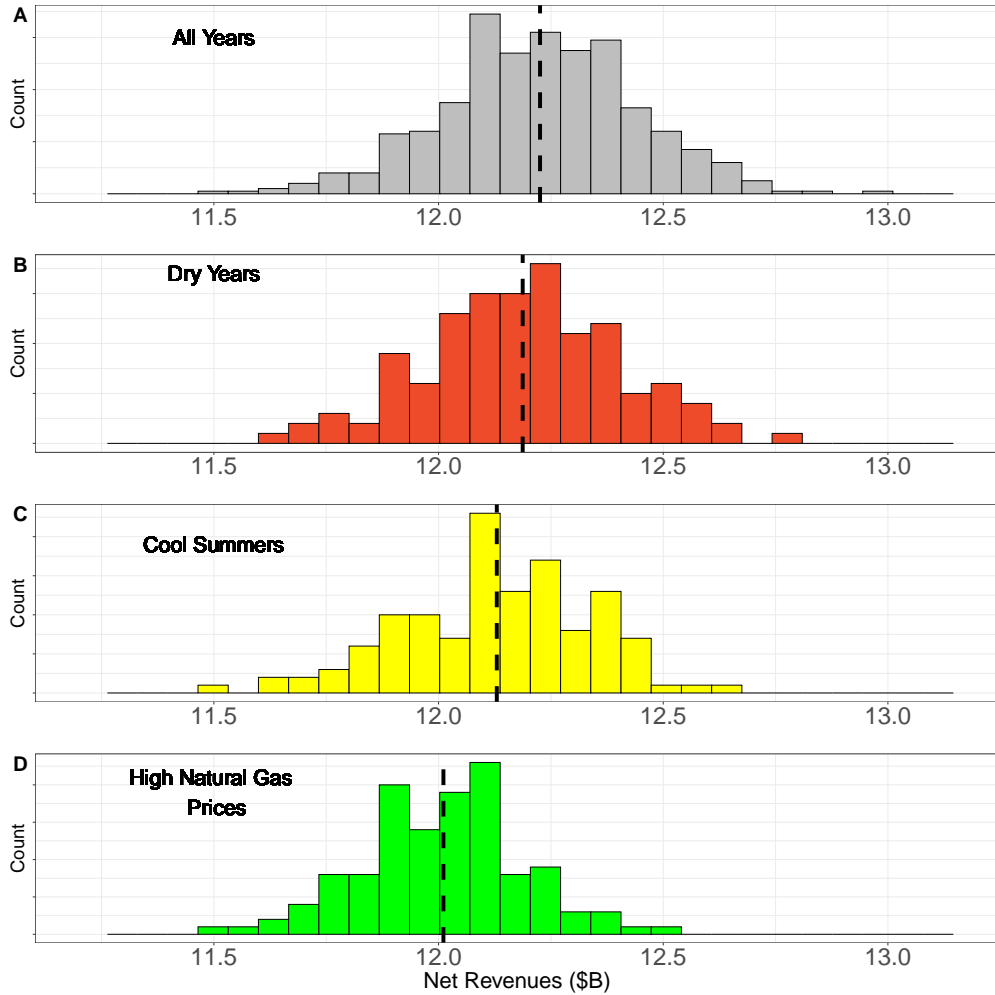

Figure S3: PG&E's annual net revenues (in \$ billions) - (A) Unmanaged net revenues across the all simulation years. (B) - Unmanaged net revenues during the dry years. (C) - Unmanaged net revenues during cool summers. (D) - Unmanaged net revenues during years with high natural gas prices.

Figure S4: Correlation between Market Price (\$/MWh) and Natural Gas Prices (\$/MMBtu) across the simulations.

1184 **Note C: Composite Index Regression and Contract Strike Selection**

Coefficients	Estimate	Standard error	p-value	Significance codes
Intercept	12.23	4.44e-03	$< 2e^{-16}$	***
Annual Streamflow	0.074	4.44e-03	$< 2e^{-16}$	***
CDD	0.108	4.46e-03	$< 2e^{-16}$	***
Natural Gas Prices	-0.161	4.43e-03	$< 2e^{-16}$	***

Table S1: **Composite Index Regression.** Output from regressing net revenues against annual streamflow, CDD and natural gas prices. The composite index is the predicted values generated using this regression. (\* Significant at 0.05. \*\*Significant at 0.01. \*\*\*Significant at 0.001).

Figure S5: Scatter plot of the net revenues and fitted values. The red and black points refer to the testing and training datasets. The mean training and testing error is 7.7 and 7.8 million respectively.

Figure S6: Simulated time series of unmanaged net revenues (in black) and those managed with the composite index contract (in red). The dotted lines at the bottom denote the minimum values (i.e. revenue floor), whereas the dotted lines at the center denote the managed and unmanaged means across all the simulation years.

Figure S7: Simulated time series of unmanaged net revenues (in black) and those managed with the composite index contract (in red). The dotted lines at the bottom denote the minimum values, whereas the dotted lines at the center denote the mean across all the simulation years.

1185        Setting the strike of the composite index contract to a lower value (10th per-  
1186 centile of the index) lowers the premium of the contract compared to higher strike  
1187 as payouts are triggered less often. This also results in a smaller decrease in net  
1188 revenue variance compared to using a higher strike. The choice of strike depends  
1189 on the risk aversion of the utility, with higher strikes indicating more risk aver-  
1190 sion.

Table S2: Performance of the composite index contract at different strike levels.

	<b>Unmanaged Net Revenues</b>	<b>Strike @ 10<sup>th</sup> percentile</b>	<b>Strike @ 20<sup>th</sup> percentile</b>
Premium (\$M)	–	29.7	64.17
Expected Payout (\$M)	–	9.34	23.59
Loading (\$M)	–	20.39	40.58
Mean Net Revenue (\$M)	12,226	12,205	12,185
Net Revenue Variance (\$M) <sup>2</sup>	47,280	40,237	33,998
Net Revenue 5 <sup>th</sup> Percentile (\$M)	11,870	11,892	11,928
Minimum Net Revenue (\$M)	11,475	11,730	11,792

1191 **Note D: Pollution Tax Scenario and Composite Index Regression**

Figure S8: Influence of pollution tax on unmanaged net revenues under the no tax scenario (grey) and with the implementation of the pollution tax (pink). The red and grey lines refer to metrics corresponding to the pollution tax and no tax scenario. The solid lines denote the mean, whereas the dashed lines denote the minimum values across the simulation years.

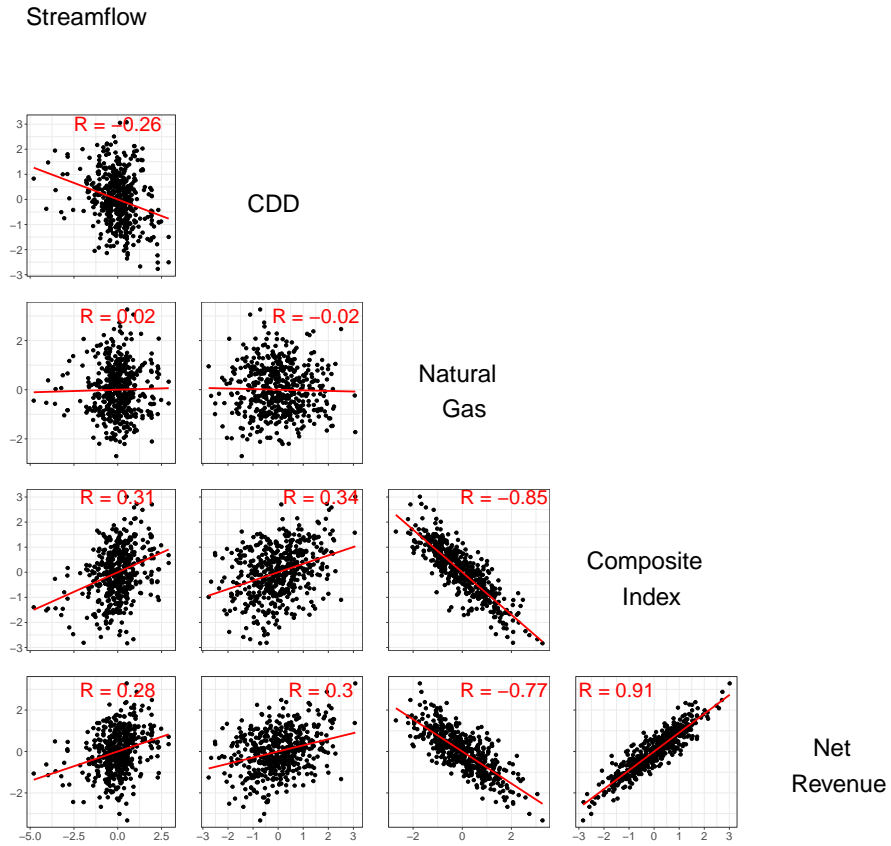

Figure S9: Correlation matrix of annual streamflow, CDD, natural gas prices, the composite index, and net revenues for the pollution tax scenario. All values are standardized. The pearson correlation coefficients for each variable pair are denoted in red within the sub-plot.

Coefficients	Estimate	Standard error	p-value	Significance codes
Intercept	11.9	5e-03	$< 2e^{-16}$	***
Annual Streamflow	0.094	5e-03	$< 2e^{-16}$	***
CDD	0.091	5e-03	$< 2e^{-16}$	***
Natural Gas Prices	-0.18	5e-03	$< 2e^{-16}$	***

Table S3: **Composite Index Regression for the Pollution Tax Scenario** Output from regressing net revenues against annual streamflow, CDD and natural gas prices. The composite index is the predicted values generated using this regression. (\* Significant at 0.05. \*\*Significant at 0.01. \*\*\*Significant at 0.001).
