Highlights

- First study on the effect of aqueous ions on the degradation of waste form for I-129
- First summary on probable iodine release pathways in various aqueous environments
- Enhanced iodine release by enhanced ion-exchange, basic pH, and ionic strength.
- Discovered secondary phase vanadinite Pb$_5$(VO$_4$)$_3$Cl and hydroxylvanadinite Pb$_5$(VO$_4$)$_3$OH
- Low ionic content and neutral pH are vital to the disposal safety of nuclear waste
Abstract

To ensure the safe disposal of nuclear waste, understanding the release process of radionuclides retained in the nuclear waste forms is of vital importance. Iodoapatite Pb_{9.85}(VO_4)_{6}I_{1.7}, a potential waste form for iodine-129, was selected as a model system for ceramic waste forms in this study to understand the effect of aqueous species on iodine release. Semi-dynamic leaching tests were conducted on bulk samples in cap-sealed Teflon vessels with 0.1 mol/L NaCl, Na_2CO_3, Na_3PO_4, and Na_2SO_4 solutions under 90 °C, fixed sample surface area to solution volume ratio of 5/m, and periodic replacement of leaching solutions. The reacted solutions were then analyzed by Inductively Coupled Plasma-Mass Spectrometry and Inductively Coupled Plasma-Optical Emission Spectrometry; the leached surfaces were characterized by X-ray diffraction, scanning electron microscopy, and infrared spectroscopy. The result shows that, compared to deionized water, the ion-rich solutions enhanced the iodine release as a result of the increased ionic strength, reduced activity coefficient of dissolved species, and increased solution pH. Surface reactions can lead to the formations of secondary phases by ion-exchange and precipitation. These findings suggest that an ion-rich environment in the geological repository can be detrimental to the disposal safety of the nuclear waste form.
1 Introduction

Nuclear energy is emission-free. The deployment of nuclear energy is motivated by the pressing demand to mitigate climate change.¹ Sustainable development of the nuclear energy requires concrete plans to safely dispose radionuclides waste generated by nuclear fission.² Among those radionuclides, iodine-129 is particularly challenging to handle due to its long half-life (15.7 million years), high yield (0.7% yield per fission of uranium-235),³ and weak interactions with common materials in repository environments such as engineering barrier and rock in geology formation.⁴,⁵ Iodide (I⁻) is the most stable form of iodine in an environment with pH and redox potential typically found in nature.⁶–⁸ Under highly oxidizing conditions, iodide can be oxidized to iodine (I₂) and/or iodate (IO₃⁻). All these iodine species are highly mobile in nature given their high volatility and or high solubility.⁹,¹⁰ Iodine, as an essential element for human health, can accumulate in human bodies.¹¹ For a healthy adult, 30% of the total iodine, approximately 15-20 mg, is concentrated in the thyroid gland.¹² Chronical radiation from iodine-129 beta decay can induce cancer to the thyroid follicular cells.¹¹ Therefore, iodine-129 is a primary contributor of the radiation dosage when analyzing the safety of disposal environments.⁴ The immobilization of iodine-129 is one of the critical research subjects for nuclear waste management.⁴,¹³–¹⁸

The most probable scenarios that compromise nuclear waste forms in a repository environment are the contact with aqueous solutions.¹⁹,²⁰ In a typical repository, nuclear waste forms are packed into corrosion resistant metallic canisters underground.²¹ Canister corrosion and degradation are anticipated to be the result of corrodents carried by groundwater.²² Through infiltration and percolation of precipitation and groundwater aquifer, water can reach the canisters and supply corrodents to react with the canister material. Upon the breaching of the
canister, the waste forms are exposed to an aqueous environment. Owing to the long half-life of iodine-129, it is crucial to predict the long-term chemical durability of iodine waste forms. To enable such prediction, it is necessary to obtain a fundamental understanding of corrosion mechanisms of waste forms and how iodine in the host material is released in various solutions that may occur under repository conditions.

Several waste form materials including glass, ceramics, glass-ceramics, cement, and composite have been proposed to immobilize iodine. These waste forms immobilize iodine via two major mechanisms: encapsulation and incorporation. To encapsulate iodine, the host matrices need to contain iodine in a designated phase different from the host material. One example is zeolite structure, in which iodine-bearing phases can be adsorbed on zeolite’s framework. Iodine can also be incorporated as a compositional element into the host matrix structure through chemical bonding, such as iodoapatite Pb$_5$(VO$_4$)$_3$I and sodalite Na$_4$(AlSiO$_4$)$_3$I.

The difficulty to study the durability of different waste forms varies on a case-by-case basis. It is particularly challenging to evaluate the encapsulation waste forms due to the complexity of multi-phase and microstructures. On the other hand, characterizing the corrosion mechanism can be relatively straightforward for single-phase crystal waste forms which have well-defined crystal structures and simple microstructures. Based on the simplicity of its crystal structure and microstructure, iodoapatite is chosen in this study as the model system of ceramic waste forms that can incorporate radionuclides. In addition, apatite ceramics is a promising material due to its thermal, mechanical, and chemical stability. These advantages are also demonstrated in nature as apatite has been found as a retention matrix for actinides and fission products in natural fission reactors at Franceville basin in Africa.
Several chemical durability tests have been performed on single-phase crystal waste forms. Uno et al. in 2001 conducted soxhlet leach method on apatite Pb_{10}(VO_4)_6I_2. Soxhlet leach method is designed to maximize the number of leachable constituents in leachant by allowing a continuous contact between the waste and recycling leachant in a closed system. The iodine release rate, 3.98×10^{-5} g⋅cm^{-2}⋅d^{-1}, was reported. Guy et al. in 2002 studied apatite Pb_{10}(VO_4)_{4.8}(PO_4)_{1.2}I_2 dissolution in aqueous solutions. The resulting data shows that iodine release was incongruent and exhibited dependency on temperature and pH. They also discovered a secondary phase, lead vanado-phosphate, precipitated at the sample surface. Zhang et al. in 2007 performed static leaching test on Pb_{5}(VO_4)_3I powder in a basic KOH/KHCO_3 buffer solution. Spectroscopic evidences show that OH^- and CO_3^{2-} can substitute I^- and VO_4^{3-} in apatite. Maddrell et al. in 2014 conducted static leach tests on crushed powder iodide sodalite Na_4(AlSiO_4)_3I in KOH/KHCO_3 buffer solutions. The result suggests a congruent dissolution. Three leaching static experiments with durations of 3, 7, and 14 days exhibited a logarithmic increase of iodine release. More recently, in 2017 Coulon et al. applied static leaching technique to study the iodate-substituted hydroxyapatite in deionized water and groundwater. They reported that the iodine release is controlled by congruent dissolution under unsaturated conditions and controlled by diffusion through ion exchange under saturated condition. Interestingly, when groundwater was used as leachant, secondary phase hydroxyapatite precipitated on the sample surface. Based on these studies, static leach test is a preferable method to study the waste form durability due to the following reasons: 1) its simple procedure can accommodate a wide range of test conditions; 2) the resultant data can be used to interpret the release mechanism. Static leaching method assumes that the solution feedback is negligible, which is valid under conditions of sufficiently low surface to volume ratio. However, the
solution feedback can gradually increase over time in a static leaching experiment. In cases where the solution is oversaturated for phases of low solubility, secondary phases can precipitate at the leached surface. Therefore, it can be problematic to use data from static leaching tests to predict waste form behavior in a repository environment. To address the issues of solution feedback, a semi-dynamic leaching method was implemented by Zhang et al. in 2018 to quantify the processes involved in the iodine release of an iodine-bearing apatite. In their experiment, deionized water solutions, as the leachant, were replaced periodically to minimize the solution feedback. They demonstrated that iodine released from apatite is driven by short-term diffusion and long-term matrix dissolution. This semi-dynamic approach was employed to produce essential datasets to parameterize a mechanistic model suitable for predicting the kinetics of iodine release under different conditions.

Since the aqueous systems in natural environment contain a variety of dissolved species, it is necessary to understand how these aqueous species affect the iodine release from iodine waste forms in an aqueous environment. For instance, the iodine release from apatite structured materials can be enhanced by rapid substitution of halogen element or inhibited by precipitation of secondary phase. In this study, we conducted semi-dynamic leach tests on single phase crystal ceramics of iodoapatite in 0.1 mol/L NaCl, Na$_2$CO$_3$, Na$_3$PO$_4$ and Na$_2$SO$_4$ solutions. The goal is to examine the impact of the solution chemistry on the kinetics of iodoapatite dissolution. We hypothesized that dissolved aqueous species, via ion exchange and precipitation, can substantially impact the dissolution kinetics; this effect should highly depend on the chemistry of the aqueous species and the surface reactions of specific phases. The finding of this study is expected to provide important insight into the long-term performance of iodine waste forms and guidance to improve the disposal safety of nuclear waste.
2 Experimental

2.1 Materials and methods

Our samples, obtained from previous studies\textsuperscript{25}, were dense ceramic chips in quadrilateral shape: 4.7 – 10.3 millimeter long by 1.1 – 1.8 millimeter thick with a chemical composition of $\text{Pb}_{9.85}(\text{VO}_4)_6\text{I}_{1.7}$ according to the EDS and X-ray diffraction refinement, as shown in Figs. 1, 2 and 4. The iodoapatite samples were synthesized by using high energy ball milling (HEBM) and spark plasma sintering (SPS) techniques. Sample surfaces were polished by 4000-grit sandpaper on a mechanical polishing wheel lubricated with ethanol. Details of the synthesis and characterization of these samples were reported previously in separate publications\textsuperscript{25,29,37}

The leaching method was adopted from ASTM C1308 standard test, as described in the previous study\textsuperscript{29,37}. Four parallel experiments were conducted simultaneously for 14 days in four different leaching solutions: 0.1 mol/L NaCl, 0.1 mol/L Na$_2$CO$_3$, 0.1 mol/L Na$_3$PO$_4$, and 0.1 mol/L Na$_2$SO$_4$. Sample surface area (m$^2$) to solution volume (m$^3$) ratios (S/V) of all four tests were fixed and maintained at 5/m. The leached solutions were replaced every 24 hours. All reactor vessels were weighed before and after each interval to monitor the solution losses which were within 0.5 % of the initial solution mass. In addition, a control test was conducted in deionized water under identical conditions for 7 days using the same protocol. All samples after leaching experiments were collected, rinsed by deionized water and ethanol, and air-dried.

2.2 Characterization
The elements of interest in the leachate solutions are I, Pb, and V. The leached solutions, depending on the solution chemistry, were analyzed by Inductively Coupled Plasma-Mass Spectrometry (ICP-MS, PerkinElmer Elan 9000) and/or Inductively-Coupled Plasma-Optical Emission Spectrometry (ICP-OES, SPECTRO Ametek Spectro ARCOS). Two standard solutions from Inorganic Ventures were used in the solution analysis: 1) $1.001 \pm 0.007 \, \mu g/\, mL$ iodide in $H_2O$ solution and 2) $1.000 \pm 0.007 \, \mu g/\, mL$ lead and $1.000 \pm 0.006 \, \mu g/\, mL$ vanadium in 1% $HNO_3$ solution. Chemical properties of solution at equilibrium state such as pH, ionic strength, speciation, and activity were calculated by Visual MINTEQ package.

Samples were characterized by Scanning Electron Microscopy (SEM), Infrared spectroscopy (IR), and X-ray diffraction spectroscopy (XRD). SEM images were taken by a FEI Quanta SEM system with FEI Versa 3D DualBeam. Infrared spectroscopy was performed on a Thermo Nicolet Continuum Infrared Microscope under Specular Reflection mode and transmission mode with a fixed incident angle and an aperture area of 10 by 10 $\mu m$ covering 4000 to 650 cm$^{-1}$ at a spectral resolution of 2 cm$^{-1}$. XRD data were collected from PANalytical Empyrean X-Ray Diffractometer equipped with monochromated Cu-K$\alpha$ radiation ($\lambda = 1.5406 \, \text{Å}$), operated at 45 kV, 40 mA, a step size of 0.026$^\circ$, and a scanning range from 5 to 100$^\circ$.

The crystal structures were refined by Le Bail algorithm using Jana2006 program. All parameters were refined by the least-squares method. The pseudo-Voigt function was used as the peak profile function. Structural parameters of $Pb_{9.85}(VO_4)_6I_{1.7}$ measured by Audubert et al. were used as initial input (hexagonal, space group P63/m, a = b = 10.422 Å, c = 7.467 Å, $\alpha = \beta = 90^\circ; \gamma = 120^\circ$).
3 Results

3.1 Leached surface characterization by SEM/EDS

In Fig. 1 (a-c), no changes observable by naked eyes occurred on the surfaces of samples leached by NaCl and NaSO₄ solutions for 14 days, whereas white layers were gradually formed on the sample surfaces leached by Na₂CO₃ and Na₃PO₄ solutions within the first week of the experiments. The SEM images in Fig. 1 (d-i) show that the surface alterations on samples leached by NaCl and Na₂SO₄ solutions were moderate, similar to the water leached surface. However, samples leached by Na₂CO₃ and Na₃PO₄ solutions demonstrated significant surface corrosion and possible formation of new phases. The surface leached by Na₂CO₃ exhibited large grains, while congregated structures of similar size appeared on the surface leached by Na₃PO₄.

According to EDS analysis, the surface chemical compositions in Fig. 2 indicate considerable changes between the leached samples and the pristine one. The key features of EDS spectrum of pristine iodoapatite are: a carbon peak at 0.3 keV from background (carbon tape), an oxygen peak at 0.5 keV, a broad Pb band from 2.34 to 2.45 keV shouldered with two small Pb peaks at 1.8 and 2.6 keV, three iodine peaks at 3.9, 4.2, and 4.5 keV, and vanadium peaks at 4.9 and 5.4 keV. Overall, the iodine peaks at 3.94 keV are nearly diminished in the EDS spectra of all four leached surfaces. The samples leached by NaCl and Na₃PO₄ exhibited a substantial amount of chloride and phosphorus signals at 2.62 and 2.01 keV, respectively. On the sample leached by NaCl, the Pb peak at 2.62 keV is comparable to the Pb peak at 1.8 keV, while the 2.62 keV peaks of the rest samples are much weaker than their corresponding 1.8 keV peaks. Carbon signal at 0.27
keV from Na$_2$CO$_3$ leached sample cannot be properly quantified due to the background interference from carbon tape and the graphite impurity introduced during sample synthesis. Sulfur EDS peak at 2.31 keV overlaps with the broad central peak of Pb at 2.34 keV. Na$_2$SO$_4$ leached surface exhibited no sulfur peak near 2.3 keV given the resemblance of the band shape between the sample leached by Na$_2$SO$_4$ and the rest. We noticed variations of carbon and oxygen EDS signals among these samples which were induced by the instrumentation settings such as sample orientation and beam parameters. Therefore, carbon and oxygen were not considered in the EDS analysis.

### 3.2 Leached surface characterization by IR analysis

The IR spectroscopy results are listed in Fig. 3. All these four samples yielded two main peaks near 750 and 890 cm$^{-1}$, which are attributed to V-O bond.$^{34}$ Pristine iodoapatite and samples leached by water, Na$_2$SO$_4$, and NaCl showed nearly identical spectra. Surfaces leached by Na$_2$CO$_3$ and Na$_3$PO$_4$ exhibited position shifts of these two V-O peaks to the region of 700 to 900 cm$^{-1}$ and multiple new bands. Sample leached by Na$_2$CO$_3$ yielded sharp bands near 785, 890, 960, 1200, and 1450 cm$^{-1}$, in which the broad band at 1450 cm$^{-1}$ is attributed to the stretching vibration of CO$_3^{2-}$.$^{44,45}$ The Na$_3$PO$_4$ leached surface generated IR peaks near 785, 870, 950, 1110, 1420, 1800, and 2200 cm$^{-1}$, in which some can be assigned to the PO$_4^{3-}$ (e.g. $v_1$ – 950 cm$^{-1}$, $v_3$ – 1100 cm$^{-1}$).$^{44}$ Interestingly, both CO$_3^{2-}$ and PO$_4^{3-}$ leached surfaces showed visible OH$^-$ stretching vibration near 3500 cm$^{-1}$,$^{34,44}$ which also occurred on water leached surface under IR transmission mode.$^{29}$

### 3.3 Leached surface characterization by XRD
The XRD data are shown in Fig. 4. All these leached samples demonstrated substantial differences compared to the pristine sample. Based on the XRD pattern, these leached samples can be categorized into two groups: I) surfaces leached by NaCl and Na$_2$SO$_4$ solutions, the pristine, and water leached sample; II) surfaces leached by Na$_2$CO$_3$ and Na$_3$PO$_4$ solutions, which were similar to the standard hydroxylvanadinite. The XRD patterns of Group I are alike, which indicates no substantial structural changes compared to the pristine. The XRD patterns of Group II display enhanced peak splitting between 25° and 28°. The original peak splitting of the pristine sample reflects the apatite structure deformation which accommodates the relatively large iodide incorporated in the apatite framework. The peak splitting of Na$_2$SO$_4$ leached surface is slightly enhanced, compared to the pristine, but is weaker than the water leached sample. Interestingly, NaCl leached surface yielded a diminished splitting at 26° and a new peak occurred at 29°, later identified as 1$ar{3}$1 shown in Fig. 5. The Full Width at Half Maximum (FWHM) of XRD from NaCl leached surface was considerably broadened to ~0.4° compared to ~0.2° from other samples, which may be attributed to the peak overlapping resulting from the presence of a secondary phase. Both Na$_2$CO$_3$ and Na$_3$PO$_4$ leached samples exhibited nearly identical XRD pattern, resembling the pattern of standard hydroxylvanadinite Pb$_{10}$(VO$_4$)$_6$(OH)$_2$. The two highest bands on Pb$_{10}$(VO$_4$)$_6$(OH)$_2$ standard are 112 and 1$ar{3}$1 with an order of intensity $I_{112} < I_{1ar{3}1}$. Same bands 112 and 1$ar{3}$1 also have the highest intensity on Na$_2$CO$_3$ and Na$_3$PO$_4$ leached samples, however, the intensity of 112 is higher than that of 1$ar{3}$1, $I_{112} > I_{1ar{3}1}$.

The Le Bail method was applied to obtain structural information from the XRD data. Table 1 compares the refined lattice parameters between sample surfaces of different
conditions and standards. No noticeable changes occurred in the crystal structures of samples leached by deionized water and Na$_2$SO$_4$ when compared to that of pristine sample (their length of $a$-, $b$-, and $c$-axes are approximately $\sim$10.4, $\sim$10.4, and $\sim$7.5 Å, respectively). On the other hand, a $\sim$0.2 Å contraction along both the $a$- and $b$-axes were observed for the samples leached by Na$_2$CO$_3$ and Na$_3$PO$_4$ solutions while the $c$-axis remains the same and is consistent with other samples at $\sim$7.45 Å. The observed and calculated diffraction patterns, the residual and the indices of the main reflections of NaCl leached sample are shown in Fig. 5. We identified a secondary phase vanadinite Pb$_5$(VO$_4$)$_3$Cl, indicating the substitution of iodine by chlorine during NaCl leaching.

3.4 Solution composition analysis by ICP-MS and ICP-OES

The results of the solution analysis on the leachates collected from the leach tests are shown in Fig. 6. The release rates of iodine, lead, and vanadium are depicted as green circles, blue squares, and red triangles, respectively. In Fig. 6(a), iodine release in NaCl solution gradually increased over time, reaching a maximum rate near 0.8 mmol/m$^2$/d at day 11, and then slightly decreased near the end of the 14-day test. The Pb and V release exhibited similar patterns with a relatively high initial rate around 0.075 mmol/m$^2$/d, then gradually decreased, and eventually approached a plateau near 0.05 mmol/m$^2$/d. In Fig. 6(b), the release patterns of iodine and vanadium in Na$_2$CO$_3$ are similar: release rates rapidly reached maximum near day 2 and then gradually decreased over time approaching a plateau. However, the long-term rate of Pb in Na$_2$CO$_3$ appears to be constant. In Fig. 6(c), the iodine release in Na$_2$SO$_4$ exhibited a high initial rate approximately 0.32 mmol/m$^2$/d and then its rate gradually decreased, eventually approaching a plateau around 0.15 mmol/m$^2$/d. Despite no high initial release, the Pb and V release patterns follow the
trend of iodine release: gradually decreased over time and then rebounded near day 10. The Fig. 6(d) describes the element release of iodoapatite in Na$_3$PO$_4$, which shows constant rates of ~4.5, ~3.5, and ~13 mmol/m$^2$/d for the release for iodine, Pb, and V, respectively. Due to the instrumentation limitation and sample consumption, only four leachates from the Na$_3$PO$_4$ experiment was analyzed for their Pb content.

Leaching rates of I, Pb, and V based on the solutions analysis are compared in Figs. 7(a-c), respectively. In general, leaching tests conducted in the ionic solutions present significantly higher element release rates than those of deionized water in the order of Na$_3$PO$_4$ > Na$_2$CO$_3$ > Na$_2$SO$_4$ > water, except in the NaCl solution. In Fig. 7(a), iodine release from Na$_3$PO$_4$, Na$_2$CO$_3$, and Na$_2$SO$_4$ solutions exhibited a long-term leach pattern similar to that of water leaching: started with a high initial release, then gradually decreased, and eventually stabilized and reached a plateau. The iodine release in NaCl solution, however, presents a different pattern: iodine rate increased from the beginning of leach test to day 11, when the rate reached maximum and then stabilized. The release rates of Pb and V from NaCl test are relatively constant but not higher than those of water leached as shown in Figs. 7(b, c).

The molar ratios in leachate solutions are illustrated in Figs. 7(d, e). Except for the anomalous NaCl data, the long-term I/V ratios in Fig. 7(d) fluctuate around the ratio of water-leached sample within the range of [0.34, 1.02], which are higher than the stoichiometric value 0.28. In Fig. 7(e), the long-term Pb/V ratios of NaCl and Na$_2$SO$_4$ tests are 1.36 and 1.65, approximate to the stoichiometric value 1.64, whereas the long-term ratios from Na$_2$CO$_3$ and Na$_3$PO$_4$ tests are 0.95 and 0.27, significantly lower than 1.64.
3.5 Overview of leaching rates in solutions

The phases of interest in this study are the aqueous solutions and the solid surfaces. The leachate solution chemistry in Fig. 7 shows that iodine release from the sample leached by the NaCl solution has a distinctive pattern. For the other leach tests, the long-term iodine rates (plateau region in Figs. 6-7) are at least one magnitude higher than that from water leaching. And the order of iodine leach rate, based on solution analysis in Fig 7 (a), is consistent with the orders of Pb and V rates in Fig. 7 (b, c): $R_{\text{Pb/V/I}}(\text{Na}_3\text{PO}_4) > R_{\text{Pb/V/I}}(\text{Na}_2\text{CO}_3) > R_{\text{Pb/V/I}}(\text{Na}_2\text{SO}_4) > R_{\text{Pb/V/I}}(\text{deionized water})$. In the following section, we will analyze the anomalous result of NaCl leach test and then explain how element release behaviors differentiate due to the different solution chemistry, such as pH and ionic species.

4 Discussion

4.1 Anomaly of the sample leached by NaCl solution

Iodoapatite sample leached by 0.1 mol/L NaCl solution exhibited unique surface phase composition and iodine release pattern. The XRD data in Figs. 4 and 5 show leached surface has no apparent splitting in the region from $25^\circ$ to $28^\circ$ ($2\theta$) and a new peak ($1\bar{3}1$), attributed by a vanadinite phase. This anomaly suggests a reduced structural distortion, which can be contributed by substituting iodide with smaller chloride. The refinement in Fig. 5 confirmed new phase vanadinite was formed on the surface, which resembles the XRD pattern of iodoapatite Pb$_{9.85}$(VO$_4$)$_6$I$_{1.7}$. The XRD data is consistent with the EDS result and solution analysis. The Pb EDS band at 2.6 keV, in Fig 2, is comparatively enhanced due to the overlap by chlorine signal at 2.6 keV. The release
rates of iodine from the NaCl test in Fig. 6(a) suggest the new phase was growing until the equilibrium state was reached. A similar iodine release pattern was observed in a pH 4 semi-dynamic leaching experiment, of which the rate anomaly was caused by the formation of a secondary phase. The molar ratios of Pb/V in Fig. 7(e) approximate to the stoichiometric value 1.6, indicating a congruent dissolution of Pb and V. The variation of I/V molar ratios in Fig. 7(d) is consistent with that of iodine rates in Fig. 6(a). Both the I/V ratios and iodine rates suggest an incongruent release for iodine, unlike the congruent Pb and V. The SEM images in Figs. 1(b, e) show that both surfaces leached by NaCl and deionized water share similar morphology. The new phase vanadinite Pb$_5$(VO$_4$)$_3$Cl, confirmed by the XRD refinement, suggests ion-exchange process between iodide and chloride. This postulation is supported by the solution and surface analysis that 1) a significant amount of iodine was released into NaCl solution while the Pb and V rates are comparable to the data of water leach test as shown in Figs. 6-7; 2) the surface alteration revealed by SEM in Fig. 1 and the surface chemistry by EDS in Fig. 2 resemble those of deionized water. Interestingly, the structural deformation of the original iodine-bearing apatite Pb$_{9.85}$(VO$_4$)$_6$I$_{1.7}$ appeared to be restored in the chlorine-substituted structure vanadinite Pb$_5$(VO$_4$)$_3$Cl. Given that the ionic radius of chloride (Cl$^-$, 1.68 ± 0.19 Å) is considerably smaller than that of iodide (I$^-$, 2.11 ± 0.19 Å), exchanging the iodide with smaller chloride seems to have repaired the structural deformation.

4.2 Effect of pH on iodine release and secondary phase formation

The solution pH has a strong effect on the iodine release of the iodoapatite. Chemical properties of the leaching solutions calculated by VMINTEQ are listed in Table 2. According to our previous studies, iodoapatite dissolution in deionized water can be
represented by the congruent release of Pb and V.\textsuperscript{29} In Fig. 7 (b, c), the Pb and V rates from different solutions are generally constant, indicating a constant-dissolution controlled process. The overall dissolution rates from low to high appears to be: $R_{(\text{deionized water})} < R_{(Na_2SO_4)} < R_{(Na_2CO_3)} < R_{(Na_3PO_4)}$, which corresponds to the solution pH values $\sim$6.1, $\sim$6.2, $\sim$10.3, and $\sim$10.9 under 90 °C as listed in Table 2. Therefore, increasing pH from neutral to basic can increase the iodine release by enhancing the overall dissolution of the iodoapatite, which is consistent with previous experimental results on synthetic iodoapatite and natural apatites\textsuperscript{33,47}. However, due to the secondary phase formed in Na$_2$CO$_3$ solutions, the dissolution process was being continuously hindered by the accumulating precipitates. Interestingly, the trend of iodine released in Na$_2$CO$_3$ solution of pH 10.3 resembles that of leaching iodoapatite under pH 4.\textsuperscript{37} Despite the rate difference, both surfaces leached by pH 4 and pH 10.3 formed secondary phases (chervetite and hydroxylvanadinite, respectively). Our previous study showed that the equivalent long-term rate of iodine release under pH 6 is 8.1 mmol/m$^2$/d, over two magnitudes higher than that of the deionized water 0.036 mmol/m$^2$/d.\textsuperscript{37} Nevertheless, the release rates of iodine leached by the solutions of non-neutral pH are at least one magnitude higher than that of the neutral pH solutions due to the enhanced dissolution process.

Surface characterizations indicate the presence of new phases under the basic conditions. The XRD analysis in Fig. 4 and Table 1 shows the surfaces leached by the Na$_2$CO$_3$ and Na$_3$PO$_4$ solutions were dominated by secondary phases resembling hydroxylvanadinite Pb$_{10}$(VO$_4$)$_6$(OH)$_2$. The SEM in Fig. 1 reveals different grain shapes and sizes from the water leached, while the EDS in Fig. 2 demonstrates that iodine was
depleted on the surface. The solution analysis also supports the formation of new phase given the similar element release pattern to that of pH 4 and incongruent Pb/V ratios far away from the stoichiometric value. As shown in Fig. 7, the leaching rates of all elements are at least one magnitude higher than the water leach rates of corresponding elements. The results from this study and those from relevant literature suggest that the solution pH exerts significant effects on the dissolution rate and the secondary phase formation in aqueous environments such as chervetite and hydroxyvanadinite precipitated under acidic and basic conditions, respectively.\textsuperscript{37,48,49}

### 4.3 Effect of ionic species on the dissolution rate

In this study, dissolved species affected the sample dissolution process by increasing the ionic strength in solution, which consequently reduced the activity coefficient of dissolved species. As a result, saturation state and solution feedback were reduced, which in return increased the dissolution rate.\textsuperscript{47} Although the 0.1 mol/L Na\textsubscript{2}SO\textsubscript{4} and 0.1 mol/L NaCl solutions have approximately the same solution pH as deionized water, the dissolution rates in these ionic solutions are significantly higher than that of the deionized water. As shown in Table 2, 0.1 mol/L Na\textsubscript{2}SO\textsubscript{4} solution gives total ionic strength of 0.26 mol/L, 0.1 mol/L NaCl solution 0.098 mol/L, and deionized water 2.04×10\textsuperscript{-6} mol/L close to zero. The vast difference in ionic strength leads to different degrees of saturation state. The activity coefficient of the major ions Na\textsuperscript{+}, Cl\textsuperscript{-}, and SO\textsubscript{4}\textsuperscript{2-} in these ionic solutions are ranging from 0.25 to 0.76, considerably lower than the major ions H\textsuperscript{+} and OH\textsuperscript{-} with a respective activity coefficient 1.00 in the deionized water. The dissolution rate in 0.1 mol/L Na\textsubscript{2}SO\textsubscript{4} solution is higher than the rate in the 0.1 mol/L NaCl solution and deionized water under the same pH and reaction mechanism, as shown in Fig. 7.
Moreover, the average release rate of iodine in Na$_3$PO$_4$ (pH 10.9) is about one magnitude higher that of Na$_2$CO$_3$ (pH 10.3) despite their similar pHs. The difference in rates can be inferred from the difference in ionic strength: 0.29 mol/L for 0.1 mol/L Na$_3$PO$_4$ and 0.25 mol/L for Na$_2$CO$_3$ solution.

In addition, no substantial structure change happened to the sample leached by 0.1 mol/L Na$_2$SO$_4$ solution. It is unlikely that anion SO$_4^{2-}$ can be incorporated into apatite structure as there is no evidence from surface characterization and solution analysis to support that. No structural change was detected by the XRD characterization. The SEM images and EDS analysis in Figs. 1 and 2 show that the Na$_2$SO$_4$ and water leached surfaces have a similar grain size, surface morphology, and chemical composition. The element release rates and ratios in Fig. 7 and 8 demonstrate a similar leach behavior between samples leached by Na$_2$SO$_4$ and deionized water. The similarities in surface alteration and leaching behavior between samples leached by Na$_2$SO$_4$ and water suggest that the iodine release in Na$_2$SO$_4$ solution was controlled by short-term diffusion and long-term dissolution and the release of Pb and V is controlled by congruent dissolution. No precipitated was observed on Na$_2$SO$_4$ leached surface, which is also similar to the surface leached by water.

In terms of the surface precipitation, the SEM images in Figs. 1 (c, f) reflect intense surface alterations in the solutions of Na$_3$PO$_4$ and Na$_2$CO$_3$. The leached surfaces yielded XRD patterns similar to the standard hydroxyvanadinite Pb$_5$(VO$_4$)$_3$OH. However, significant contractions of $a$- and $b$-axes as shown in Table 2 indicate the size of VO$_4$ site was reduced, which could be caused by a substitution of smaller groups. The IR spectroscopy of the sample leached by Na$_3$PO$_4$ confirms the existence of P-O bond and
Furthermore, the EDS detected phosphorus signal, which also supports that PO$_4^{3-}$ group was in VO$_4$ site. The molar ratios of Pb/V in Fig. 7 show a deficiency of Pb relative to V in Na$_3$PO$_4$ leaching test. These evidences suggest the precipitates are a product of hydroxyvanadinite with mixed site: Pb$_{10}$(VO$_4$)$_n$(PO$_4$)$_{6-n}$(OH)$_2$. The site mixing is possible since Pb$_{10}$(VO$_4$)$_x$(PO$_4$)$_{6-x}$(OH)$_2$ can occur during wet chemistry reactions under similar conditions.$^{48}$ Carbonate is known to be incorporated into apatite structure by substitution.$^{50-53}$ Given that phosphate (PO$_4^{3-}$, ionic radius 2.30 ± 0.42 Å)$^{46}$ can replace vanadate in iodoapatite,$^{48}$ it is reasonable to presume that carbonate of a smaller ionic radius (CO$_3^{2-}$, 1.89 ± 0.19 Å)$^{46}$ can substitute vanadate in a similar crystal structure. Therefore, the secondary phase formed on in the Na$_2$CO$_3$ solution is Pb$_{10}$(VO$_4$)$_6$m(CO$_3$)$_{1.5m}$(OH)$_2$.

**4.4 Mechanism of iodoapatite dissolution and surface reactions in aqueous environments**

Fig. 8 generalizes the mechanism of iodoapatite dissolutions with multiple processes contributing to the iodine release. Our previous study on iodine release in deionized water suggests that the iodine release is driven by short-term diffusion and long-term dissolution.$^{29}$ Diffusion and dissolution are affected by various factors of the solution chemistry, such as solution ionic strength, pH, and secondary phase formation resulted from a supersaturation of the solution with respect to low solubility species. In neutral pH solutions, the iodine release is subjected to the substitution of iodine by anionic species in solution such as OH$^-$ and Cl$^-$. When dealing with solutions of comparable pH, a higher ionic strength, due to the ionic content, can enhance the dissolution by changing saturation conditions. Solution pH other than near neutral can increase the dissolution by
exponentially accelerating the dissolution process. The resulting rapid dissolution can
often lead to the precipitation of secondary phases when the solution approaches the
supersaturation state of low solubility phases. Possible secondary phases include
chervetite Pb$_2$V$_2$O$_7$ under acidic condition$^{37}$ and hydroxylvanadinite Pb$_5$(VO$_4$)$_3$OH under
basic condition.

5 Conclusions

The present study focuses on effects by solution compositions on iodoapatite
dissolution. The results suggest that the higher ionic strength can accelerate dissolution by
decreasing the activity coefficient of reacting aqueous species, thus promoting iodine
release from apatite. Non-neutral pH conditions clearly increase the dissolution rate and
often lead to precipitations of secondary phases, such as chervetite and
hydroxylvanadinite. The secondary phase precipitation at the surfaces hinders the
dissolution rate by reducing the available reacting surface area. However, the overall
iodine release rates in both basic and acidic solutions are exponentially higher than those
in the near-neutral pH conditions, especially in deionized water. Current understanding of
dissolution is mostly based on leaching experiments conducted in deionized water. Our
investigation on the impact of solution chemistry reveals new complexities of the
dissolution kinetics of crystalline waste form during environmental degradation. Unlike
fresh water with low ion content, high concentrations of aqueous species commonly
found in underground brines can compromise the chemical durability of crystalline waste
form in a geological repository. For this specific waste form, maintaining neutral pH and
low ion content in aqueous solutions is important to the disposal safety of radioactive
iodine. Since iodine is one of the most challenging radionuclides to immobilize, building
a comprehensive theoretical framework of iodine immobilization can significantly advance the research in nuclear waste disposal safety.
